# Metallurgical & Chemical Engineering

A Monthly Journal, Being the Incorporation of
Electrochemical and Metallurgical Industry
and Iron and Steel Magazine

---

## Volume XII

*From January to December*, 1914

---

436837
3. 7. 45

NEW YORK
McGRAW PUBLISHING COMPANY, Inc

# INDEX TO VOLUME XII

## GENERAL ALPHABETICAL INDEX

*Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest).*

## A

ABBE Engineering Co. 200
Abbe, P. O. 347
Abrasives. Allen. (P.) 533
Accountants. Cost accounting and the work of. Haynes 449, 614
——Ashby 549
ACID:
——Orthophtalic. Solubility. Rivett and Rosenblum 14
——Phosphoric. Haff (P.) 65
—— From Phosphate Rock. Washburn (P.) 533
——Sulphuric Contact process. Rittman 476
—— From smelters 440
—— Removal of Arsenic 353
—— Towers. Schliebs. (S.) 655
Acid-resisting Alloy. Gleason. (P.) 352
Acid tanks. Mastic lining 353
Addicks, Lawrence 425
Æsop at Niagara Falls 71, 214
Agriculture and Chemistry. Baekeland 564
Air Compressor. Nash 423
Air valves 232
Alaska. Development 394
Alaska Gold Company 248, 460
Alaska: Southeastern. Advantages for hydro-electrochemical industries. Lass 337
Alby United Carbide Factories 34
ALLOYS:
——Acid-resisting. Gleason. (P.) 352
——Aluminium. McAdams. (P.) 352
——Binary. Rapid Cooling. Gulliver. (S.) 595
—— Argental and macademum 360
—— Ormiston 649
——Babbitt Metal. Determination of Copper 753
——Bronze. Dewrance. (S.) 594
——Bronze. Three-metal Blow 461
——Bureau of Standards Analyzed Brass Samples 80
——Copper - Aluminium. Read and Greaves. (S.) 595
——Copper-Rich Kalchoids. Hoyt 30
——Copper, Tin and Zinc. Hoyt 644
——Definition. Thatcher 430
——German Silver. Metallography. Thompson 785
——Gun Metal. Effect of temperature 597
——Heating in Vacuo. Thorneycroft and Turner 787
——Iron and Steel Hadfield 598
——Iron-Nickel-Copper. Clamer. (P.) 413
——Manganese Bronze Corse 113
——Manganese bronze Skillman and Corse 113
——Melting points of copper alloys 102
——Muntz Metal Stead and Stedman. (S.) 596

ALLOYS: (Continued.)
——Platinum and tungsten and molybdenum. Weintraub 475
——Pyrophoric. Faebr. (P.) 660
—— Patent Decision 218
——Tungsten and Nickel. Kressler. (P.) 728
Alumina. Determination in iron ores. Wurzel 430
ALUMINIUM:
——Alloys argental, macadamum 360
——Alloy. McAdams. (P.) 352
——Alloy. Ormiston 649
——Alloys with Copper. Read and Greaves. (S.) 595
——Calorizing 730
——Density. Brislee 14
——Electroplating upon. Loeb. Mies. (D.) 800
——Light Strong Castings 619
——Ore production 290
——Precipitant for Cyanide Solutions. Butters. (S.) 351
——Purifying. Mellen. (P.) 352
——Solder. (P.) 66, 352
——Wire. Electrolytic insulation. Chubb and Skinner 712
Alundum. High-Temperature Resistivity. Northrup 125
Amalgamating in cyanide solutions. Randall 248
——See also Gold and Silver.
Amalgams of Sodium. Electric Conductivity. Nanstone 14
Amberg, Dr. Richard 485
American Bottle Company 440
American Bridge Co. 165, 355
American Chemical Society 360, 494
——Montreal Meeting Postponed 550
——New York Section. Chemical and Dyestuff Committee Report 753
American Clay Company 440
American Cyanamid Company. Niagara Works 265
American Electrochemical Society 221, 368, 419, 514, 619
——New York meeting. Report 327
——Niagara Falls Convention. Report 703
——New York Section 419
American Foundrymen's Association 550
——Chicago Convention 641
American Gas Institute. Chemical Section 677
American Institute of Chemical Engineers. New York meeting 55
——Philadelphia Meeting 756
——Troy Meeting 376, 434
American Institute of Metals 550, 588
——Chicago Convention 641
American Institute of Mining Engineers 189, 296, 304, 366, 416, 514
——Utah Meeting 589
American Iron and Steel Co. 62
American Peat Society 788
American Platinum Works 360

American Rapid Cyaniding Co. 734
American Rolling Mill Co. 424
American Smelting & Refining Co. 194, 212, 288
American Zinc, Lead & Smelting Co. 432
AMMONIA:
——Analysis. Stach. (S.) 655
——From Calcium Cyanamide. Cooper. (P.) 480
——From Coal Gas 699
——Synthesis 477
——Ammonia process for zinc and copper ores. Bretherton. (P.) 139
——Ammonia soda process. Theory. Mason 571
Anaconda Copper Mining Co. 432
Anaconda-International Consolidation 366
Anaconda. Model Town 618
Anaconda. Progress in Metallurgy 737
Analcid Method 793
ANALYSIS:
——Ammonia. Stach. (S.) 655
——Analoid Method 793
——Calorimetric of Gold in Cyanide Solutions 460
——Carbon in iron and steel. Brown 390
——Chromium in iron and steel. Walters. 310
——Coal in U. S. 62
——Copper in Babbitt Metal. Hagmaier. 753
——Electrometric titration. Ziegel 705
——Fine-meshed Brass Gauge as Substitute for Platinum in Electro-analysis 87
——Gas 677
——Gold and Platinum Assay. (S.) 480
——Grading by Elutriation. Stadler. (S.) 536
——Lead determination at Broken Hill. (S.) 54
——Natural gas. Brown 168
——Nickel, Marsh 709
——Phosphorus in phosphor bronze. Hagmaier 524
——Phosphorus in Scheelite Concentrates. Hagmaier 620
——Radium. Schlundt 709
——Silica and alumina in iron ores. Wurzel 430
——Tin Ores and Concentrates.
—— Hutchin. (S.) 350
—— Wraight and Teed. (S.) 350
——Zinc determinations at Broken Hill 138
——Zinc in Bronze Coins. Rose 326
Annealing Brass and German Silver Wire. 483
Annealing malleable castings. Storey 383
Anticorrosion lead oxide deposit (D.) 543
Anticorrosive Magnetic Oxide Deposit. 425, 736
Anti-Corrosive Pickling Chains and an Acid-pump Casting 206
Antimony. Metallurgy. Cowan 643
Anyox Smelter 676
Apparatus for Determining the Hardness of Metals by the Brinell Method. 205

Appleby, William R. .... 735
Arc light with unconsumed electrodes. Vosmaer .... 377
Argental .... 360
Arizona Copper Co. ...34, 104, 222, 269, 684
Arizona Copper Smelter. Unit Construction Cost. Jones. (S.) .... 653
Arizona. New Copper Smelter .... 11
Arms and the Man .... 488
Arsenic. Removal from sulphuric acid .... 353
Asbestos. Uses in Chemistry and Metallurgy .... 356
Ashland Fire Brick Co. .... 580
Askenasy, Prof. Paul .... 485
Atomic Weight. Indefiniteness. Fajans and Hönigschmid .... 495
Atomic Weight of Lead .... 487
Atom. Structure, and high-frequency spectra .... 363
Auld Company .... 541
Aurora Consolidated ....493, 556
Austin, A. Obituary .... 542
Austin, J. F. .... 542

B

BABBITT metal. Determination of Copper. Hagmaier .... 753
Badger & Sons Co., E. B. .... 360
Badger Chemical Diary .... 360
Bag House in Lead Metallurgy. Anderson. (S.) .... 654
Baekeland, Leo H. .... 541
Baer, W. P. .... 426
Bailey, Gilbert E. .... 475
Baily, T. F. .... 141
Bakelite for Commutator Insulation .... 603
Baker & Co. .... 360
Baker Suspension Bin .... 120
Bamberger, Ernst .... 799
Bancroft, W. D. Portrait .... 335
Barber Asphalt Paving Co. .... 258
Baron, H. J. .... 799
Barrows .... 46
Baryte in California .... 722
Barytes. Separation from Zinc Blende. Greenstreet. (P.) .... 659
Bath processes for wood waste. Teeple .... [illegible]5
Battery. Railway Track Cell. Marshall .... 342
Bayonne Bolt & Nut Company .... 4[illegible]
Beer. Chill-proof. Patent suit .... [illegible]
Benzol from Coal Gas .... 702
Bethlehem Steel Company .... 306
Bicarbonate of soda and sawdust for extinguishing fires .... 105
Biddle Hardware Co. .... 68
Bins for blast furnaces. Design .... 117
Bin. Suspension Storage. McKee .... 605
Bismuth from Copper. Thum. (P.) .... 479
Bismuth. Nitric Acid Treatment .... 583
Bitumen and electric mains explosions .... 80
Blair, Robert S. .... 735
Blake, Lucien I. .... 541
BLAST FURNACE:
—Blowers. McQuigg .... 286
— Johnson ....230, 311
—Bosh. Lead. Anderson. (S.) .... 782
—Flue Dust Handling. (S.) .... 481
—Flue Dust. Nodulizing. Addicks. (S.) .... 654
—Flue dust. Baggaley. (P.) .... 139
—Gas cleaning and utilization. Johnson ....685, 760
—Heat Balance. Cornell .... 747
—Lead. Palmer. (S.) .... 654
—Oil-fired. Copper .... 492
—Stack. Shannon. (P.) .... 351
—Use of raw fuel. Prudhomme. (P.) 351
—See also Iron and Steel.
Blaugas. Manufacture and use. Lieber .... 153
Blowing Engines. Gas .... 734
Blowpiping, quantitative, as aid to prospector. Fischer ....693, 771
Boiler Plant for Blast Furnace. Johnson. 171
Boilers. Prevention of Scale .... 180
BOOK REVIEWS:
—American Fertilizer Hand Book .... 544
—Aubert & Rogers. Industrial Chemistry .... 211
—Brame, J. S. S. Fuel, solid, liquid and gaseous .... 800
—Carrier. Engineers' Handbook of the Buffalo Forge Company .... 486
—Classen. Quantitative Analysis by Electrolysis .... 212
—Gowland. Metallurgy of the Non-Ferrous Metals .... 668
—Hall. Steel Foundry .... 486
—Heather. Electrical Engineering for Mechanical and Mining Engineers .... [illegible]1
—Hooker. Chloride of Lime in Sanitation .... [illegible]11
—Hoover, L. H., & Hoover, H. B. Agricola's De Re Metallica .... 14[illegible]
—Johnson. Chemical Analysis of Special Steels .... 668
—Keeney & Lyon. Electric Furnaces for Making Iron and Steel .... 544
—Kindl. Rolling Mill Industry .... 544
—Liebig. Zink und Cadmium .... [illegible]0
—Lyon and Keeney. Electric Furnaces for Making Iron and Steel 544
—Mennicke. Die Quantitativen Untersuchungsmethoden des Molybdäns, Vanadiums und Wolframs .... [illegible]

BOOK REVIEWS. (Continued.)
—Mineral Industry. Edited by G. A. Roush .... 736
—Müller. Elektrochemisches Praktikum 610
—Noble. Fabrication de l'Acier .... 610
—North. Laboratory Experiments in General Chemistry .... 211
—Rogers & Aubert. Industrial Chemistry .... 211
—Stansfield. Electric Furnace .... 212
—Wagner. Cleaning of Blast Furnace Gases .... 800
—Weed. Copper Handbook .... 426
—Wren. Organometallic Compounds of Zinc and Magnesium .... 544
Borax .... 661
Borchgrevink Process .... 381
Boron. Weintraub .... 185
Boyer, F. T. .... 609
Brackett & Co., F. W. .... 799
Bradley, Fred W. .... 799
BRASS:
—Bureau of Standards. Analyzed Samples .... 80
—Corrosion. Whyte and Desch. (S.) 595
—Corrosion. Influence of Coke... 724, 787
—Economy of electric melting. Gillett and Lohr .... 647
—Electric Brass Melting from Central-Station Viewpoint. St. John .... 646
—Electric Furnace. Helberger. Dorsey 644
—Electric Melting with Hering furnace. Clamer and Hering .... 648
—Electrolytic deposition of. Bennett and Davison .... 340
—Fine Meshed as Substitute for Platinum in Electroanalysis .... 87
—Furnace Practice .... 540
—Pyrometers for molters. Gillett .... 648
—Resistivity, solid and molten. Northrup .... 161
—Use of gas in melting .... 648
—Vanadium in. Dunn and Hudson. (S.) .... 594
Brick, Silica and Clay. Relative thermal conductivity. Marshall .... 74
Brick, Paving, from Blast Furnace Slag 43
Bridgeport Testing Laboratories .... 66
Brinell hardness. Derihon apparatus .... 205
Briquets. Channel Furnace for burning. Rameo. (P.) .... 353
Briquets. Coal .... 360
Briquetting Fine Ore. Methesius. (P.) .. 657
Briquetting Iron Ores. Crusius. (P.) .... 788
Briquetting. Ronay. (P.) .... 262
Bristol Co. ....208, 357, 605, 797
British Aluminium Co. .... 394
British Geological Survey .... 448
British Westinghouse Co. .... 325
BRONZE:
—Determination of phosphorus in phosphor bronze. Hagmaier .... 524
—Determining Zinc in Bronze Coins .... 326
—Dewrance. (S.) .... 594
—Manganese. Corse .... 113
—Manganese. Skillman .... 113
—Pyrometers for molten. Gillett .... 648
—Three metal. Blow .... 461
Brown Hoist Bins .... 118
Brown Hoist Machinery .... 48
Brown Instrument Co. .... 208
Bruce, Stuart S. .... 667
Buffalo Forge Co. .... 171
Buffalo Mines Co. .... 493
Bunker Hill & Sullivan Mining Co. .... 258
Bunsen Society, German. Leipzig meeting .... 495
Burch, Albert .... 541
Bureau of Mines. .62, 78, 150, 198, 366, 436, 460, 540, 678
—New Buildings at Pittsburgh .... 311
—Policy. Holmes .... 334
Bureau of Standards .... 588
—Analyzed Samples .... 80
Burgess, C. F. .... 277
Burner. Dunn Powdered Coal .... 94
Burro Mountain Copper Co. .... 288
Busch-Sulzer Bros. Diesel Engine Co. .. 347
Butte and Superior ....99, 222, 618
Butters, C. ....268, 277
Butz, H. A. .... 735

C

CADMIUM. Electrodeposition. Marble and Mathers .... 339
Cadmium in glass. Sullivan .... 188
Calcium carbide. Alby Factories .... 34
Calcium carbide. Pure. Preparation. Thompson .... 779
Calcium cyanamide. Landis. (P.) .... 53[illegible]
Calcium cyanamide. Niagara Works .... 265
Calcium Cyanamide. For Ammonia Production. Cooper (P.) .... 480
California. Chemical resources in. Dolbear .... 720
California. Mineral output .... 422
Callon, J. M. ....141, 541, 609
Calorimeter. Adiabatic. Riche .... 606
Calorimeter. Fery Gas .... 650
Calorimeter. Recording Gas .... 662
Calorimeter. Recording. Stone and Hinman .... 6[illegible]8
Calorizing .... 730
Calumet & Hecla .... 556
Cameron, Angus .... 141
Camp Bird .... [illegible]7, 744
Carbon Electrodes. Skin Effect. [illegible] 223
Carbon. Energy of vaporization. Hering [illegible]
Carbon, Granular, Calcination and graphite production. Brown. (P.) 727
Carbon, [illegible]. Tone .... 710
Carbon tetrachloride for extinguishing fires .... 105
Carnegie, Andrew .... 43
Carnotite concentration. 14[illegible], 365, 89, 146, 36[illegible]
Carnotite in Utah .... 49[illegible]
Carnotite, Prospecting .... 15[illegible]
Carnotite, Radium to Uranium Ratio in Carnotite (S.) .... 65[illegible]
Carveth, Hector R. .... 60[illegible]
Castings, Electric steel. Hansen .... 335
Castings, Study of the annealing process for malleable. Storey .... 383
Castner Electrolytic Alkali Co. .... 419
Caustic and chlorine. Mercury cathode. Le Sueur .... 61
Caustic soda by electrolysis. Diaphragm cell. Dow (P.) .... 480
Caustic soda. Diaphragm cell. Byrnes (P.) .... 534
Cell, Primary. Effect of alternating current .... 264
Cell, Railway track. Marshall .... 342
Celluloid. Absorption of gases .... 180
Celluloid. Hyatt .... 13[illegible]
CEMENT:
—Chemistry of salt water cement. Taft ....26, 27
—Portland. Testing. (P.) .... 194
—Thomas Mellen Co. .... 104
—Production in 1913 .... 198
—Recovery of dust from kilns. Carpenter and Fleming (P.) .... 66
—Testing. Gadd .... 130
Chain Belt Company .... 543
Chain belt. Steel .... 543
Chain drive. Sileot .... 347
Chandler Foundation Lecture. Frost. Baekeland ....427, 446, 557
Channing, J. Parke .... 485
Chapman Engineering Co. ....206, 440
Chart recording instrument .... 208
Chase, C. A. .... 210
Chemical and dyestuff industry 55[illegible], 679, 684, 75[illegible]
Chemical industries as affected by characteristics of electrical energy. Steinmetz .... 329
Chemical industries. Effect of legislation. Wagner .... 15
Chemical industry in Russia .... 104
Chemical industries of U. S. and the war. Nichols, Toch, Matheson, Hesse, Mattos .... 551
—Stone .... 679
Chemical industries of U. S. Chemical and Dyestuff Committee report 753
Chemical resources of California. Dolbear .... 720
Chemical versus physical actions in furnaces. Hering .... 439
Chemistry. The dependence of industries on. Pierce .... 614
Chemistry. Industrial Aspects of. Baekeland .... 55[illegible]
Chemistry in America .... 66[illegible]
Chemistry. Industrial. Some economic aspects. Hesse .... 594
Chemistry. Manufacturing possibilities [illegible]1
Chemistry. Physical. Application to industrial processes. Rittman .... 4[illegible]5
Chemists' Club. Presentation of bronze bust of Morris Loeb. .... 220
Chemists' Club. Tango .... 283
Chemists. Professional obligations. Whitaker .... 43[illegible]
Chemists' slide rule. Lee .... 2[illegible]
Chile, Chuquicamata. Development of copper leaching and electrolytic precipitation. Smith .... 29[illegible]
Chino Copper Co. .... [illegible]
Chlorate of potash in Norway .... 576
Chloridizing ores at Silver City, Utah [illegible]
Chloridization of ores. Dry. Malm .... 128
Chloridizing roasting. Ledoux (P.) .. 14[illegible]
Chloridizing sulphide ores. Forland (P.) . [illegible]4
Chlorination of ores. Christensen and Holt. (P.) .... 65[illegible]
Chlorination at Park City .... 431, 4[illegible]
Chlorination in Utah .... 22[illegible]
Chlorine and caustic. Mercury cathode. Le Sueur .... 6[illegible]
Chlorine by electrolysis. Diaphragm cell. Dow (P.) .... 48[illegible]
Chlorine. Diaphragm cell. Byrnes (P.) 534
Chlorine for detinning. Von der Linde. (P.) .... [illegible]90
Chlorine. Production and products. Baekeland .... 56[illegible]
Chrome ore in California .... 72[illegible]
Chromium. Determination in iron and steel. Walters .... 31[illegible]
Church, John A. .... 45[illegible]
Cie des Forges & Aciéries Électriques Paul Girod .... [illegible]
Clam shell filter press. Sweetland .... 5[illegible]
Clark, H. C.
Clark, William W. .... 66[illegible]
Classics. Quotations from .... 216
Clay brick and silica brick. Relative thermal conductivity. Marshall .... [illegible]4
Cleaning laundry work. Electrolytic (P.) .... 60[illegible]

Clennell, J. E. .... 141
Close, Fred .... 541
Coal analysis in U. S. .... 62
Coal briquets .... 360
Coal. Carbonization. Harger .... 264
Coal gas residuals. Wagner .... 696
Coal. Powdered. Burner for. Dunn, Roush .... 19
Coal. Powdered. Burner for. Dunn.
Coal. Pulverized. Lord. (S.) .... 53
Coal tar colors in America. Stone .... 679
Coal tar industry and the war. Matheson, Hesse, Matos .... 552
Cobalt, Ont., Canada. Ore treatment. Parmelee .... 467, 507
Cobalt and alloys. Kalmus .... 184
Cobalt. Separation from copper and nickel. Hybinette. (P.) .... 531
Cobalt-silver ores. Dyckerhoff. (P.) .... 412
Collins, George E. .... 609
Colorado Iron Works Co. .... 420
Colorado metal production in 1913 .... 539
Colorado School of Mines .... 222, 269
Colors. Coal tar in America. Stone .... 679
——Matheson, Hesse, Matos .... 551
Colors, Mineral, in California .... 722
Color photography of microstructure of ores. Rigg .... 30
Columbia University .... 295
Columbia University. School of Mines. 50th anniversary .... 168, 347
Combustion. Flameless or surface. Bone. 325
Commutator insulation. Bakelite .... 603
Compass. Gyroscopic. Scott and Rozie. 786
COMPLEX ORE PROBLEM:
——Austin .... 300
——Bell .... 297
——Bleecker .... 375
——Bretherton .... 374
——Canby .... 301
——Choate .... 430
——Clerc .... 471
——Clevenger .... 298
——Collins .... 298
——Croasdale .... 369
——George .... 373
——Godbe .... 302
——Godshall .... 471
——Guess .... 300
——Haldane .... 374
——Hoskin .... 372
——Ionides .... 375, 674
——Johnson .... 370
——Monell .... 490
——Motherwell, H. .... 549
——Motherwell, W. .... 490, 549, 673
——Parks .... 370
——Richards .... 370
——Scibird .... 373
——Skinner .... 371, 548
——Swart .... 297
——Thomson .... 371
——Traphagen .... 300
——Wiard .... 301
——Editorial summary .... 472, 555
Compressed air for lifting solutions in quantity. Phelps .... 391
Compressing air and gases. Nash .... 423
Compressors. Gas-engine driven .... 743
CONCENTRATION:
——Carnotite .... 365
—— Fischer .... 146
—— Kithill and Moore .... 89
——Complex sulphides from Mary Murphy mine. Collins .... 243
—— Parmelee .... 21, 217
—— Keedy .... 157
——Development of methods in 1913 .... 5
——Dry concentration and flotation at Joplin .... 492
——Dry jigging unsized ore .... 555
——Electrostatic separation. Wentwood. (S.) .... 782
——Flotation and cyaniding .... 221
——Flotation antimonial silver ore. Campbell. (P.) .... 198
——Flotation litigation decision .... 362, 366
——Flotation of lead and copper ores .... 77
——Flotation. Minerals Separation Co. 77
——Flotation. Oil. At Butte and Superior .... 222
——Flotation. Selective Horwood process. (S.) .... 350, 414
——Igneous of metallic values from mixed sulphides. Clerc..250, 307, 490
——Isbell concentrator for unsized or unclassified ore-pulp .... 601
——Magnetic separator. Ulrich. (S.) .. 536
——Old tailings. Silver Lake .... 11
——Round table at Great Falls. Crowfoot. (S.) .... 783
——Tin at Geevor Mill, Cornwall, (S.). 262
Condenser tubes. Corrosion. Bate. (S.). 656
Conduction. Electric. At high temperatures. Northrup .... 340
Congress. International engineering .... 11
Congress. International, of Mining, Metallurgy, Engineering and Economic Geology .... 392
Congress. International, of Tropical Agriculture .... 101
Conklin, H. R. .... 69
Consolidated Ores Co. .... 493
Contact process for sulphuric acid. Rittman .... 476
CONVERTER:
——Basic copper Magnetite linings. Wheeler and Krejci. (S.) .... 138
——Basic lined copper at Old Dominion. Howard. (S.) .... 654
CONVERTER: (Continued.)
——Bessemer. Bretand. (P.) .... 529
——Copper. Haas. (S.) .... 535
——Copper matte. Herreshoff. (P.) .... 728
——Lead matte at Tooele. Kuchs. (S.). 654
——Tropenas vs. electric furnaces for the manufacture of steel castings. Muntz .... 379
Converting copper. Improvements .... 144
Converting. Cost of power for air .... 537
Conveyors. Weighing the continuous flow of materials .... 206
Cooler for roasted ore. Hanington. (P.). 791
Cooler. Ore. Laist. (P.) .... 352
Cooper Co., C. & G. .... 743
COPPER:
——Alloys with aluminium. Read and Greaves. (S.) .... 595
——Alloy with nickel and copper. Clamer. (P.) .... 413
——Alloys with tin and zinc. Hoyt .... 644
——Ammonia process. Bretherton. (P.). 139
——Analysis in Babbitt metal. Hagmaier .... 753
——Basic-lined converter practice at Old Dominion. Howard. (S.) .... 654
——Basic-lined copper refining furnace. Addicks and Brower. (P.) .... 195
——Bessemerizing. Matte - Herreshoff. (P.) .... 728
——Butte and Duluth. Costs .... 269
——Cathode. Reproducibility of. Getman 706
——Chloridizing leaching at Park City. Holt .... 593
——Combination smelting and converting furnace. Knudson. (P.) .... 64
——Converter. Haas. (S.) .... 535
——Converting. Improvements in .... 144
——Copper-nickel ore treatment. Borchers and Pedersen. (P.) .... 659
——Copper-tin, copper-zinc, copper-phosphorus and copper-aluminium alloys. Blow .... 461
——Copper-tin-lead alloys. Blow .... 462
——Effects of repeated remelting. Clements .... 644
——Electrolytic production of flat perforated copper tubing for radiators. Feldkamp .... 67
——Electrolytic process. Frasch. (D.) .. 142
——Extraction from large boulders. Craney. (D.) .... 142
——Factors affecting the cost .... 379
——Filtration of flue dust from furnace gases. Rigg. (P.) .... 531

## The Business Outlook

There is a fortune in store for the inventor who can make a perfect looking glass. Most mirrors reflect the bleak and garish rays and make a person look worse than he really is.

A shrewd New England business man recently told us a story in point. He was feeling tired and nervous one day as he sat in a barber's chair—he could not get people to pay him what they owed him, the government were spoiling business, his workmen would not work, his lunch was not digesting, and it was raining outside. As the barber asked him whether he wished a tonic for his hair, he was shocked and grieved at the aged countenance reflected in the grim mirror. He looked at the barber's face in the glass. This fat and eupeptic representative of the race that conquered all Gaul and carried the victorious eagles to Ultima Thule, looked a sick, fat, flabby-faced, chicken-hearted degenerate son of the heroic masters of the world. Then he looked at the tonsorial artist directly. His poor weak brain could hardly believe his eyes. The barber he saw was really a well-nourished, charming man, who, with an education, might have served his adopted country well as a diplomat. The business man had the saving grace of a keen sense of his own limitations. He said to himself, said he: I am a poor mutt. The mirror is a darned poor mirror, and the mirror is a deus-ex-machina. At all events he quit worrying and sensibly went to work.

Now what is known as a business tone and financial sentiment has periods of distortion of view just as did this business man. Things are never as they seem, and things never seem as they are. Every perception contains truth and falsity. For instance, a year ago the metallurgical concerns of this country were running at full blast and prices of metal were high. Now the reverse is too true. People were then optimistic in the main. Now the reverse is true.

There have been many events that have tended to depress economic values—the Balkan war, the Mexican trouble, and in this country the long delay of tariff and currency legislation, and above all the poor corn crop of 1913. But if in holding the mirror up to industry we conclude that things are in a bad way, are we not making the same mistake as our business friend did? Let us ask ourselves how good are things.

About the only good thing we know of in industry is honest work and sincere intelligence. Intelligence is the faculty that gives us a knowledge of facts and tells how to foresee the coming of facts. While the unintelligent majority is wasting things, the intelligent minority is saving things. There are people in all classes, the aristocrats of democracy who make two blades of grass grow where one grew before, who raise social values, who make life worth living. They are humble and proud, they are strong and weak, they are rich and poor, but they all put honest effort into their work, they understand the ethics of a good job, and they cheat neither society, their employer nor themselves. Their final and ultimate reward is a consciousness of duty well-done and a recognition by their compeers. Without this intellectually dominating minority this world would be a poor place.

Now, if not all signs of the times deceive us, it will be this type of man in all classes of human activity that will decisively shape the future. For ourselves in our limited field we may say that this journal will continue to strive its best to act as a clearing house of chemical and metallurgical ideas, of chemical and metallurgical facts, of chemical and metallurgical figures so that the efficiency of chemical and metallurgical operations may be increasingly higher. Efficiency is the keynote of the coming transition period in industry, and as it is eminently sane, we cannot help looking with hearty optimism into the future and thus we extend to our readers the compliments of the season.

---

### Progress in Copper Metallurgy

As indicated in our previous annual reviews, the metallurgy of copper is now on such a basis that no striking innovations in smelting and allied processes have been made in recent years. In hydrometallurgy, however, the work of the past year leads us to suggest that we are on the eve of a remarkable development in this line. The success of experimental work already points to possibilities in reducing tailing losses and in making available vast quantities of copper-bearing material that hitherto have been untouched or regarded as waste.

In the preliminary preparation of copper ores by wet methods for concentration, the Hardinge conical mill, in an exhaustive test at Miami, proved itself superior to the Chilean mill in practically every particular and will be used generally in this class of work.

The handling of slime at Anaconda has been solved more satisfactorily than before, by means of Dorr thickeners and round tables. The round table is one of the oldest, but at the same time one of the most efficient machines for the concentration of extremely fine material. The objection to its use, however, has been its small capacity compared to the large amount of floor space required. A round table is usually from 20 to 30 ft. in diameter and has a capacity of about 6 tons of feed in 24 hours. By building tables with multiple decks, capacity per square foot of floor space is very greatly increased. Twenty-deck tables, with a daily capacity of 120 tons each are now in use, and tables with even 30 decks have been considered. Centrifugal concentration, which at one time appeared very promising, is abandoned temporarily at least, for these modified slime tables. Flotation methods, so generally used in the concentration of zinc ores, are slowly gaining ground for the treatment of copper ores.

The hydrometallurgical treatment of copper ores is rapidly advancing. About a dozen plants are now successfully treating copper ores or tailings by wet methods; and the number will almost certainly increase, for several companies are conducting experiments along this line. It is expected, for example, that an experimental plant for the treatment of copper slime by continuous counter-current decantation will be erected this year, making use of a principle which has been widely adopted in cyaniding slime. The mechanical thickeners for this plant will be constructed of acid-proof material.

The 80-ton hydrometallurgical plant of the Anaconda company is operating successfully and is the precursor of a much larger plant which will be erected to treat the daily tailing production as soon as a number of minor details are worked out in this commercial-experimental plant. The presence of silver renders necessary an oxidizing-chloridizing roast, and the results in silver and copper extraction and in cost of treatment have been very gratifying. Roasting is accomplished in modified MacDougal furnaces, having two fire boxes arranged so that their flames can be delivered to the third or fourth floor from the top. The third floor was finally adopted. The temperature is maintained at 1200° F. for oxidizing and at 1000° F. for chloridizing.

For complete roasting 3.56 per cent coal is required. Dust losses are small, ranging around 2 per cent. The recoverable percentages of silver and copper are 93.4 and 84.9, respectively. The cost for coal, acid and salt is estimated at $0.175, $0.096 and $0.07, respectively. The leaching solution contains 8 per cent. sulphuric acid and 10 per cent salt, and is used at a temperature of 85° C. The time required for extraction is about two and one-half hours. The total cost of treatment is estimated at 70 cents per ton, which makes the cost of producing copper from one-half per cent tailing seven cents per pound. The method of precipitating copper and silver from solution has not yet been finally adopted.

Two plants in Butte, the Butte & Duluth and the Bullwhacker, are operating on the oxidized surface ores of this district, using a sulphuric acid leach and electrolytic precipitation. The Butte & Duluth has recently changed its method of operation. Formerly the ore was crushed to ¼-in. mesh and leached in vats. Now, however, the ore is ground to about 8 or 10 mesh and slowly run through a series of very long Dorr classifiers, with counter-current washing in order to dissolve the copper and wash the solution from the ore. By this process the ore is exposed to acid for a shorter time, with less dissolution of such impurities as iron and aluminium, and with greater extraction of copper.

A modification of direct acid leaching is used at Braden, where a "neutralizing" leach with partly charged acid precedes the "acid" leach. Precipitation is electrolytic. At Chuquicamata the ore, mainly brochantite, is leached with dilute sulphuric acid and the solution is electrolyzed. In this case the acid accumulates in solution by additions from the ore itself.

The Bradley process, which has been tried at Anaconda for the treatment of slime, has not yet proved a commercial success, and the plant has been closed for several months.

At Great Falls, as a result of some very careful experimental work, the capacity of MacDougal roasters has been increased from 46 to 77 tons cupreous material per day, the sulphur in the calcines being 7.9 per cent and 8.9 per cent, respectively. With the increase in capacity there has been an accompanying decrease in the labor required. A resume of results shows 270 and 180 furnace men employed, under the old and new practice, respectively. The average number of furnace men employed per 100 tons of cupreous material was 1.52 and 0.93, and of feeders 0.59 and 0.44, respectively, under the old and new practice.

The sintering of copper ores has not made the progress accomplished with lead ores, mainly because of the fact that the need for such treatment is not nearly so necessary. Some isolated cases of sintering and agglomerating with slag have been noticed, but the practice has not been generally adopted.

The development in converting copper matte has been not only in the continued use of basic linings, but also in the adoption of much larger converters than were in general use in past years. Converters of the upright-cylinder type, 20 ft. in diameter, are being very generally adopted and tonnages of many thousands on a single lining are the order of the day.

The dismissal of the famous Anaconda smoke suit by the Supreme Court is the final chapter in this prolonged fight and spells peace at least in Montana. In California the appointment of a commission to pass upon the many phases of the smoke situation will tend to bring order out of the chaos which has existed in that state for so many years. In Utah the situation is not very different from that of the past five or six years.

The invention of William A. Hall, by means of which the sulphur of ores may be saved in the elemental state, is an epoch-making one, and if the promise made by experimental work is fulfilled, when applied on a commercial scale, the smoke problem may be considered solved. This invention is the more meritorious in that it brings to light reactions which hitherto have been apparently overlooked. We may expect that sulphur, the material which has caused so much trouble in the past, will soon become, instead of a menace, an actual source of profit to the copper smelter.

## Progress in Gold and Silver Metallurgy, 1913

Substantial improvement was made last year in methods of recovering gold and silver, but few striking innovations were brought forward. As has been the case in recent years, the cyanide process was the most important in point of quantity and value of metals recovered. Its use was extended to the treatment of a greater variety of ores; costs were reduced and extractions increased. Nothing of importance has occurred in the fields of amalgamation or smelting, and no data have been forthcoming from several attempts at chloridizing. The electro-cyanamide process, originally installed at the Ajax mill, Cripple Creek, was finally abandoned in favor of combined concentration and bromo-cyaniding.

A year ago we commented on the filter litigation and the successful defense of the Moore patents. At the same time we suggested that the end of the litigation was not yet in sight. The prediction was verified late in 1913, when Mr. Charles Butters filed a suit against the Golden Cycle Mining Company, Colorado, for damages for infringement of filter patents. This outcome was the more striking by reason of the fact that the Golden Cycle was one of the first to settle with the Moore company after the courts had sustained Moore's case against Butters. Mr. Butters has been active in other ways as well. In our department devoted to patents will be found a note on a new method of filter construction and operation, invented by Mr. Butters. His idea seems to be to avoid the Moore method of discharging the cake by a difference of pressure between the inside and outside of the filter leaf, and thus escape infringement of the Moore process. Another feature of the filter situation was the consolidation of the Oliver and Moore interests, possibly strengthening the position of both. On the other hand, the makers of the Portland filter, after investigating the whole matter of filter litigation, continued the manufacture and sale of their machines independently. While a number of large companies effected settlement with the Moore concern, many small users of vacuum filtration plants operated them without regard to the legal status of the business.

Consideration of the filter question naturally calls to mind the status of continuous counter-current decantation, as this process offers some measure of relief from the use of filters. Last year witnessed the greatest advances yet made in the use of this method of treating slime. Three companies abandoned filters in its favor: The Gold Road and Tom Reed, in Arizona, and the Lluvia de Oro, in Mexico; and a number of new plants adopted this method. The Gold Road company reports decreased loss both in dissolved and undissolved gold, partly due to further dissolution of metal in passing through the series of thickeners, although it was thought formerly that the plant had ample agitating capacity. Operating costs have been lowered. The quantity of cyanide used, covering both chemical consumption and mechanical loss, has been increased by not more than 1-10 pound per ton, although the ore is treated in a 2-pound solution.

At the Globe & Phoenix, Rhodesia, South Africa, a 350-ton continuous counter-current decantation plant was installed last year. Loss of dissolved gold in the tailing is reported to be only three cents per ton. A similar system was adopted by the Liberty Bell in Colorado, for the treatment of concentrates formerly sold to smelters. The new process affords a material saving to the company. In this case, in order to simplify treatment and reduce dissolved metal loss to a minimum, the tailings have been discharged into the regular mill circuit, ultimately passing out through the Moore filter. This gives the tailings additional agitation treatment and permits addition of all water at one place, *i. e.*, the filters. No additional labor has been required in the mill, and the total cyanide used is said not to be increased.

A late report from the Porcupine Crown mill, where the continuous counter-current decantation system was adopted, states that an extraction of 96 per cent is being obtained. This result is interesting in view of the fact that concentration is not practiced in this mill as in some others in the same district.

The tall form of air agitator for slime, commonly known as the Pachuca, seems to have fallen in the estimation of American metallurgists, for most of the new installations have made use of combination air-mechanical agitators, such as the Dorr and Trent. The former, first described in our issue last January, has been adopted in new mills in Nevada, Colorado, Canada and Mexico, and some older forms of agitators have been displaced in old plants by it. Experience with this form of agitator indicates low cost for power, continuity of operation and high mechanical efficiency. Sand and concentrates are readily handled, and the treatment is adapted to the chemical requirements of the ore, thereby giving high efficiency in dissolution.

The use of aluminium as a precipitant of gold and silver from cyanide solution received increased attention last year. This method is not new, having been proposed and patented in 1893 by Carl Moldenhauer; but the idea was never developed on a practical scale. Various experimenters have tried Moldenhauer's scheme, but it was not successfully used until Kirkpatrick developed the application of aluminium dust in 1908.

Dissatisfaction with zinc precipitation at the Nipissing mill, led to the investigation of the merits of aluminium, with the result that it was finally adopted. A study of conditions at this plant showed that precipitated solutions had lost their normal dissolving power, and the cause was finally attributed to the presence of zinc and arsenic in solution. Since the adoption of aluminium, no further difficulty of this sort has been experienced.

There are a number of advantages in using aluminium for precipitation. Although it is more expensive than zinc, yet much less of it is used per ounce of metal precipitated. Aluminium does not combine with alkali cyanide as does zinc, hence does not cause consumption of cyanide. When the precious metals are precipitated, all of the cyanide combined with them is regenerated. This necessitates the presence of free caustic alkali in the solution. One of the obstacles to the successful use of aluminium dust has been the difficulty of wetting it and getting a thorough contact with the solution. This is overcome by the use of some form of vortex mixer.

Another new proposal in precipitation made last year was that of MacArthur, who suggested the use of zinc wafers or small sheets. He reported very satisfactory results to the Chemical, Metallurgical and Mining Society of South Africa, but subsequent investigators in different parts of the world were unable to confirm his figures.

The old scheme of volatilizing gold and silver from sulphide ores by roasting with salt was revived last year as a new invention in Australia. As pointed out in our columns at the time, the process of volatilization had been exploited in this country over ten years ago, but for various reasons was not successful. The Australian venture also is said to have been dropped.

The development of low-grade gold mines in Alaska has resulted in plans for milling on a huge scale. At the Alaska Gastineau the development has been so rapid that each succeeding report of progress has far outdone its predecessor in reporting available ore, and the tonnage now in sight is beyond mental conception. Prospective mill capacities also have increased by leaps and bounds, and following the last visit of the promoters to the property the prospective mill capacity jumped from 6000 to 20,000 tons per day. But with ore now said to run into the hundreds of millions of tons, the present operators can project mills of almost any old capacity without depriving their descendants of an opportunity to work the property and derive some of the enormous aggregate profit now in prospect. Actual milling operations will be awaited with interest.

## Developments in the Metallurgy of Zinc in 1913

From a metallurgical point of view the status of spelter production was not materially changed during 1913. This is not to imply a dearth of experiment and research in the winning of zinc; on the contrary, there was marked activity in almost all branches of zinc-ore treatment. Some hopes have been realized, and progress has been recorded; but a reduction process has not been brought forth that can be considered a serious competitor of retort smelting.

In connection with retort smelting one item may be recorded which is of considerable advantage to the producer of zinc ore and concentrate. Hitherto the producers, particularly those whose output was small, have not benefited from any gold, silver, lead or copper which their products might contain, even though the gross value of these metals was substantial. In the case of large producers they might recover the retort residues and make a small profit by selling them to lead smelters, but such a procedure was out of the question for the small operator. More recently the zinc smelters have been offering contracts providing payment for gold, silver, lead and copper, in addition to the regular payment for zinc. The residues are then marketed by the zinc companies, and the small operator makes a profit without being put to the inconvenience of reselling small lots of residue.

This step on the part of the zinc smelters may be more or less of an experiment. Presumably it is not wholly philanthropic, and doubtless they anticipate a profit on the final transaction. The present forms of contract may be tentative, and the final form will depend on data accumulated from long experience; but the fact that other metals in zinc concentrates and ores are not to be a total loss to the producer is a matter for congratulation.

Electrolytic schemes for the reduction of zinc sulphate solution have been under close investigation during the past year. Metallurgically these processes look promising, but they seem to encounter serious economic obstacles. If we consider only the operating cost of production per pound of spelter, leaching and electrolytic reduction may show a margin of saving as compared with retort smelting; but if interest on investment and amortization of plant be included, the margin fades. This is due to the comparatively enormous cost of an electrolytic plant as compared with a retort smelter of equal capacity.

The situation with regard to electrolytic reduction in this country might be relieved if we had enormous zinc-ore deposits, so that a large tonnage could be relied upon for a long period of time. A company owning such a deposit might then erect an electrolytic plant with assurance that its cost would be distributed over a large tonnage of ore, and that the ultimate cost of spelter would not be unduly affected. But, as pointed out editorially a year ago, there are not many such deposits in the United States; our supply of zinc-ore comes from many small mines. Probably the last word has not been spoken on electrolytic spelter, and such processes will be investigated in the future; but under present economic conditions they do not constitute a serious menace to the continuance of retort smelting.

No less interest attaches to the development of electric zinc smelting. Experimental work has been unremitting and the results are encouraging. This branch of zinc metallurgy holds out hope for the direct treatment of both simple and complex ores, eliminating the present costly and wasteful intermediate processes of concentration and separation. Another attractive feature is the possibility of a high recovery of the precious metals which, in the case of a complex ore, are now subject to loss in a succession of processes. Direct smelting with electric power is probably nearer realization than it was a year ago, and there is a possibility that the coming year will witness an attempt to put it in practical operation.

The advocates of hydrometallurgical methods also have been active during the past year, and their processes have attracted the attention of spelter producers and mine operators. It was expected that chloridization would be in active operation before the year closed, but that achievement has been delayed for one reason or another, and we will have to wait for definite results of this process. Another hydrometallurgical scheme involves a sulphatizing roast with subsequent extraction in water assisted by acid treatment. The ultimate product is zinc oxide.

No definite work has been done in this country during the last year in the recovery of zinc from lead blast-furnace slags. One proposal, patented last year, suggests the treatment of such slag with lime to displace the zinc oxide, collecting the latter as it is driven off at a high temperature. The process would be applicable to molten slag as it comes from the furnace, thereby conserving much heat. Pyrometallurgical concentration of low-grade zinc sulphides and carbonates, producing crude zinc oxide for reduction to spelter, has not made further progress in this country, although the idea has not been lost sight of. The success of the Pape process in Germany, both on old slags and on crude ore, has attracted a great deal of attention, and it is not unreasonable to assume that it will soon be tried in this country. The need for some such scheme is becoming more urgent in view of the increasing quantity of finely divided concentrate produced by flotation methods. This concentrate is not desirable material for retort smelting. If it can be briquetted and converted successively into oxide and spelter, a problem now confronting the zinc smelters will be solved.

On the whole a commendable lot of work has been done toward improving present processes and in attempts to develop new ones. A great deal of time and money have been spent in investigation, and there is apparent willingness to test new ideas of merit. Apparently no line of development has been finally dropped, and the coming year should witness a nearer approach to the realization of the hopes and ambitions of different investigators.

### Developments in Concentration Methods

The record of ore concentration in the United States during 1913 is one of unusual interest. Technical literature has been replete with articles on research and practice, pointing the way to the solution of a number of problems and recording encouraging results from the treatment of ores that have been difficult to handle. Standard methods of concentration have held their own, but greater interest centers in the extension of accessory processes which must be credited with much of the improvement that has been shown in mineral recovery.

While a great deal of thought has been given to improved metallurgical efficiency, attention has been directed with increasing force to the economics of milling. Operators generally are realizing what the more thoughtful leaders have been emphasizing for some time, viz., that the highest metallurgical efficiency is not necessarily indicative of the most economic operation. In ore-dressing especially, commercial conditions must be kept in mind, and the requirements and preferences of the smelter must be considered. For obvious reasons smelter schedules favor the production of high-grade concentrates. Hence, one of the points the mill operator must keep in mind is the grade of his products. A high percentage of recovery in the form of a low grade product may not be as profitable as high-grade concentrate representing a lower saving.

Perhaps the feature that looms largest in last year's record of concentration is the wider adoption of flotation, not only for zinc but also for copper ores. This process unquestionably has made a place for itself and is accepted as a valuable addition to ore-dressing. The Minerals Separation process is in operation at two places in Colorado; it is being tested on a large scale by the Inspiration Copper Company in Arizona, and in a smaller way at numerous places in the Western states. The Butte & Superior Company, Montana, is using flotation on a large scale, treating zinc ore. The Minerals Separation Company claims an infringement of its process in this instance, and has already won a suit for damages. Pending an appeal by the defendant, the process continues in operation under an order of the court which requires Butte & Superior to make a strict accounting of all ore treated and concentrates produced by flotation. Regarding the outcome of this bit of litigation it would be hazardous to express an opinion, for past experience has shown that a legal opinion in such cases is not always consistent with sound technology. The result, however, undoubtedly will have a widespread effect on the future of flotation in this country.

In the mechanical concentration of slime no striking innovations have come forth. Multiple-deck tilting tables have found some advocates, and various forms of vanners have continued in favor. In a notable case, however, that of the Anaconda Copper Company, the buddle has found preference after a long campaign of costly experiment with various forms of slime concentrators. Twenty-deck buddles are a novelty, but they seem to be a rational development for the concentration of slime on a huge scale, and will be used at Anaconda this year. More extended reference to these machines will be found in our editorial review of copper metallurgy.

Another development at Anaconda, resulting from exhaustive tests, was the adoption of the Dorr continuous slime thickener for preparing suitable feed for the buddles. This device, well known in cyaniding, is finding extended use in concentration as a means of securing a feed of uniform consistency for flotation boxes and mechanical slime concentrators. The Anaconda installation consists of 40 four-deck Dorr thickeners, handling 20,000,000 gallons per day of water containing 2000 tons of slime. Other installations of thickeners in concentrating mills have been made by the Nevada Consolidated, Montezuma and Old Dominion copper companies. Scattered installations of these machines in flotation plants have proved valuable in preparing feed and in recovering water from tailings.

Dry concentration and separation has had an encouraging year. An elaborate testing and custom plant was erected in Denver by the Sutton, Steele & Steele Company for the demonstration of dry tables and dielectric separators. Many tests have been made and some custom work done on large lots. No new plants of this kind have been erected, but several are in prospect and may be built this year. One of the new machines brought out by this company, and now practically perfected, is an electrostatic table, being a reciprocating deck with an electrically charged surface over which the mineral particles progress by a series of jumps.

One of the most interesting and promising developments of the year was the Plumb pneumatic jig, described fully in our last issue. The features of this machine are simplicity of construction and operation, and perfect automatic control in discharge of concentrate and tailing. It offers an advantage in producing unusually high-grade concentrates, and has already attracted the favorable attention of some large operators. The coming year should witness its adoption in commercial work.

Electrostatic separation has been more widely adopted in the treatment of zinc-iron ores. Being a process of limited application, it is not in general use; but in those cases to which it is adapted, it is giving excellent results. The Huff machine has been greatly simplified in the manner of construction so that troubles incident to electrodes are believed to have been largely overcome. A good example of the conditions under which electrostatic separation is valuable will be found in the work at the Mary Murphy mill, described elsewhere in this issue.

In the preparation of ores for concentration, some new work has been done in sizing machines. Promoters of dry processes realize the necessity of reasonably close sizing, and have been trying to avoid the use of screens. Development work on the McKesson-Rice screenless sizer has been continued, and the Sutton, Steele & Steele Company has a new device for a similar purpose. Classification for wet ore-dressing has been improved and extended, although efforts are still being made to produce concentrators that will treat an unclassified feed. The new Isbell table is said to do such work with fair success. On the other hand, Prof. Robert H. Richards, always a strong advocate of classification, has recommended even greater refinements in the preparation of table feed; and, in a paper presented to the American Institute of Mining Engineers, has shown the probable benefits to be derived therefrom.

---

## Showing of the Iron Industry in 1913

Market developments of the past year, studied in the retrospect, furnish ground for some interesting conclusions. Of greatest importance, perhaps, is the fact that while general trade activity began to decrease early in the year, it was not until the beginning of October that steel mills began to operate at much less than their full capacity. Several months before that decrease occurred the mills themselves had begun to look for a decided recession in demand and there is little doubt that the majority of producers were really surprised at the way material was taken in June, July, August, and September. The unexpected usually occurs in steel, and so it was that while one would normally expect an improvement in business in the early autumn it was just at that time that the real decrease in consumptive demand began to show itself.

Steel mill operations made a wonderfully good showing in the first nine months of 1913, viewed from the standpoint of business conditions generally, and this fact may indicate something. Upon analysis, it does not appear that in any specific direction there was a particularly heavy demand. There was no great rush of public or semi-public improvements. The railroads were moderate rather than heavy buyers. The steel flowed out through a multitude of channels. The consumption of steel has very greatly broadened in the past half dozen years, and this fact can be realized by recalling the nature of demand in 1906, which was a remarkably good year. Then there was extremely heavy buying by railroads; rail production reached a total which has not since been attained, even though the total production of steel has since greatly increased. The railroads were also heavy buyers of cars, locomotives and bridge material. Many large structures, office buildings, hotels and bridges, were erected, consuming a larger percentage of the total output than is the case to-day. The tin plate production of the year, on the other hand, was 576,079 tons, whereas in 1912 and 1913 it has been about a million tons. There has been a correspondingly great increase in the production of sheets. The steel needed for the ordinary activities of the people has greatly increased, while there has not been as great an increase in the consumption of steel in the large channels, where financing is usually necessary. It has been relatively difficult to finance large projects in recent years.

These considerations furnish a basis for constructing a theory that the steel industry is undersized for the normal consumptive requirements of the country. It is not reasonable to conclude that the requirements of the ordinary people will not continue to increase, while it is hardly unfair to assume that a time is coming when large projects can be more readily financed. On any other basis it is difficult to explain why the steel industry reached a stage of full activity so readily in 1912, or why it continued its full activity so long in 1913.

A year ago, in reviewing the developments of 1912, the curious position of the merchant furnaces was referred to. It was pointed out that the year had brought an advance of about $4 a ton in pig iron, from a level which was absolutely profitless to the majority of merchant furnaces, but that three-fourths of the pig iron advance had been absorbed by advances in ore and coke, which many of the merchant furnaces must buy. The market did not seem to be giving the merchant furnaces their just due. It has all come out in the wash. There is too much merchant furnace capacity. A condition in general trade which easily gave full employment to the steel works, now supplied with pig iron almost wholly by their own blast furnaces, did not give full employment to the merchant furnaces. There has not been a sufficient increase in the pig iron requirements of foundries, malleable, gray iron and steel, to balance the increase in blast furnace capacity. Steel works have built furnaces so as to avoid buying merchant iron, and Lake Superior iron ore interests have built merchant furnaces so that they could consume their ore instead of selling it to merchant furnaces.

Largely as a result of this difference in alignment of the steel and merchant blast furnace industries to their respective markets, pig iron prices began to decline at the beginning of 1913, whereas steel products did not begin to decline measurably until August. Present pig iron prices represent a profitless level to a great many merchant producers, while the same statement cannot be made of steel products.

Despite the unfavorable trend of affairs, the year 1913 established new records throughout the iron and steel industry. Pig iron production amounted to about 31,100,000 tons, against 29,726,937 tons in 1912, which in its time was easily a record year. The production of steel ingots and castings was between 32,500,000 and 33,000,000 tons, against 31,251,303 tons in 1912. The production of rolled iron and steel was close to 26,000,000 tons, against 24,656,841 tons in 1912. Lake Superior iron ore shipments were about 49,750,000 tons, against 48,211,778 tons in 1912. The gains in production over 1912 were all effected in the first half of 1913; the second half developed production approximately at the average rate of 1912.

There is speculation as to the cause of the slump in demand which overtook the industry in the closing months of the year. Explanations drawn from recent precedents, 1907 and 1910, are quite insufficient, particularly if it be held that the present decreased demand is to continue as was the case after the recessions cited. In 1907 there was a financial panic, the unsoundness which thus culminated having been apparent for months in that no new projects of any magnitude were undertaken. Towards the close of that year practically all large work on hand was suddenly completed, bridges, buildings, railroad extensions, etc., whereas there has not been a great deal of large work in the past year, and much of the work that was in progress has not been completed. Two of the biggest jobs in steel ever undertaken, the Hell Gate bridge and approaches and the New York subway work, still involve years rather than months of work.

The decrease in demand in 1910, the latest precedent, was clearly seen later to have been due to the fact that the country stocked up with material, bought on the 1909 break in prices, the encouragement to stock up being furnished by the spectacular advance which occurred in steel prices during the second half of 1909. The stocks had to be liquidated, and the liquidation was not completed until 1911. In the past year there has been no similar stocking up; stocks are admittedly low everywhere.

Two hypotheses remain: that there is a period of decidedly bad business in store for industry in general, which would necessarily keep the steel industry from regaining a state of full operation; or that the present decreased demand for steel will prove only temporary.

The feeling so prevalent in many quarters that business is going to be bad for some time appears to come from psychological rather than physical causes. Many are disappointed that we have a Democratic administration, are disposed to be critical, and refuse to take anything on faith. But the tariff shows no signs of hurting the iron and steel industry, for October, the first month of the new tariff, showed absolutely negligible imports. The October trade balance in general, by the way, was spectacularly large, breaking all records for a month, and although not aided by harvest movement was at the rate of $1,670,000,000 a year, a rate of a billion dollars in excess of the best trade balance ever shown for a year.

If the present decreased demand for steel is only temporary, it can readily be explained. There is always, between buying movement in steel, a period of reaction during which prices fall, buyers restrict their purchases and reduce their stocks to the absolute minimum. Once it is established that a bottom has been reached, whether the period required be long or short, the market quickly revives.

## Microstructure of Raw and Manufactured Copper

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In your November issue (p. 621) in the report of a meeting of the New York Section of the American Electrochemical Society reference is made to a paper on the "Microstructure of Raw and Manufactured Copper" by Mr. W. H. Bassett, Technical Superintendent and Metallurgist of the American Brass Company. A note is made of the structural changes in copper due to working.

Some six or seven years ago, whilst engaged in electrolytic refining of copper, occasion arose to discard several lengths of conductor bars. These had a sectional area of about 4 sq. in. The smiths on the plant could not work up or draw the old leads to make use of them for other purposes. These leads were all made on the works from electrolytic copper of 99.95 per cent copper content and having conductivity varying between 100 and 101 Matthiesen standard.

Little use was made of microphotographs at that date for determining impurities in metals. Through the medium of your columns I should like to ask if Mr. Bassett has ever applied microphotography to determine whether any structural change has taken place in a conductor carrying for a period of five years, a current such as is used in copper refining.

Can any one say why such copper bars could not be worked or drawn and had always to be sent to the refining furnace to be melted.

It would be of interest also to know if any change takes place after long use of conductors carrying high voltage currents from central power stations.

*Gourock, Scotland.*

## "Hydrometallurgy—Joys of Its Theory, Woes of Its Practice"

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Referring to Mr. Malm's communication regarding chlorination of ores, I wish to mention some general points which occur to me. There is only a difference of opinion between Mr. Malm and myself as to whether this process will serve a useful purpose in producing metals cheaper than they are now produced in well-known and simple processes. All of Mr. Malm's figures for operations of this kind are based upon assumption.

Mr. Malm's process will serve a useful purpose, in my judgment, only on finely disseminated ores which are not mechanically separable. When he tries his scheme (demanding highly refined operative work) on a large daily tonnage scale, against good mechanical separation schemes, it is my opinion that he will not find the wide margin of profit he mentions in anticipation.

There are only a few mines producing complex ores of such a nature, or in such a finely disseminated state, that they cannot be separated with good milling practice. Separation processes are not usually applied at the best efficiency, because the miner, millman or mining engineer usually is not a first-class metallurgist. Consequently when one decries the failure of separation processes in such hands as these, he is not treating the possibilities fairly. And I venture to say that if some of the new complex, hydrometallurgical schemes were used by the average operator the results would be far inferior to those now obtained by mechanical processes.

There is no question in my mind that we are passing through a period of refinement in mechanical separation processes, and that these improvements will put such processes in the running with any complex chemical procedure that demands fine chemical balancing and control.

It is with regard to the comparative cost of old, proved processes, properly operated, and an estimate of the cost of his process that Mr. Malm and I cannot agree. For a long period of years it has been my privilege to compare anticipated costs with actual book costs in working chemical and metallurgical processes. One of the most difficult things that I have to contend with, and one that I find many others will not contend with, is to add enough to the proposed cost of a process to make the venture safe from a pocketbook point of view; and one of the most deplorable things is the attempted estimation of costs by persons who are inexperienced in such matters.

Just at the present time, for instance, an engineer of wide metallurgical training is working on an acid-leaching process, and has published figures on making sulphuric acid that are just about one-half what anyone else in the United States has been able to make it for; and, at that, under conditions of labor, supplies, etc., that are not as favorable as those existing at plants now in operation. I know how prone one is to under-estimate rather than over-estimate costs; and I know how process promoters err on this more than would an operating engineer.

I understand that Dr. Chauvenet's contention is that, no doubt, the costs of dry chlorination are underestimated at several points; and that, since financial profit determines the value of any process, the one in question is not considered good. In this connection I agree with Dr. Chauvenet and not with Mr. Malm.

Finally, I would like to refute the impression that has gone abroad that metallurgists engaged, for instance, in the zinc business, are asleep at the switch; that they are not competent to judge the value of various newly proposed schemes; that they want to stick to a cumbersome, annoying process rather than accept one that can be worked with regularity and ease. It is ridiculous to assume that our operating metallurgists are passing all the good things by.

*Denver, Colo.* Lewis B. Skinner.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—My discussion of hydrometallurgy, in reply to Dr. Chauvenet's article, was not intended to embrace an adverse criticism of the Malm process. The presence of a single impurity ought not to be fatal to the operation of an otherwise successful process. Further, it was my understanding that the Malm process, although advertised for a number of years, had never been put into actual commercial operation. Mr. Malm has now specifically stated this to be a fact, thus giving sufficient authority for my statement that the theory is the best part of the process.

However, since Mr. Malm has frankly suggested that I am ignorant of the subject, simply because I mentioned it incidentally, and further since he insists upon a statement from me relative to his process, I am forced to proceed with a criticism of the Malm process in greater detail.

I wish to point out the following things: (1) My understanding of the theory of the Malm process; (2) the fact that the Malm process is inoperative; (3) that the data given are incorrect and absurd; (4) my reference to the Malm process was justified by published facts.

Finally, Mr. Malm had knowledge of the paper and articles to be mentioned below, and if they were not in accordance with his results a public denial should have been made at the time. Further, the authorities quoted show such an intimate knowledge of the process, the equipment, the analyses, recovery and cost, that it is hard to believe that they were not inspired by Mr. Malm himself.

At a regular meeting of the Western Association of Technical Chemists and Metallurgists, held in Boulder, Colorado, January 4th, 1909, the Malm process was described by Dr. F. W. Traphagen, professor of metallurgy in the Colorado School of Mines.

The Malm process was specifically described in the Western Chemist and Metallurgist, in the May number, 1910, by Mr. Harry J. Wolf. The Malm process was again specifically described in the Western Chemist and Metallurgist, June, 1910, by Messrs. Jean McCallum and E. J. Bruderlin, of the Colorado School of Mines.

Details of this process after this time, so far as I have been able to ascertain, are meagre.

In case the process described in the references is not the Malm process, the matter is between Mr. Malm and the authors.

Quoting from Mr. Wolf: "In the Malm Process, or Western Metals Process, as it is sometimes called, the ore is suitably crushed, dried and subjected to the action of chlorine gas. The metals are converted into chlorides, which are dissolved and separated by methods of substitution. The zinc chloride is dissociated in an electrolytic cell of special design and the chlorine gas is recovered for reuse. The process is described more in detail as follows:"

Further: "The properly prepared ore is fed to a revolving tube of special design, in which it is subjected to the action of chlorine gas. The pulp is kept in contact with the gas long enough to chloridize 40 per cent to 70 per cent of its metal contents. The reaction between the gas and the sulphides is exothermic."

Further: "When the chloridization in the tube has been carried far enough to suit the requirements of the particular ore under treatment, the partially chloridized ore is passed from the tube into an agitator tank, where it is agitated in water or mill solutions, in the presence of free chlorine gas. Extraction is thereby completed and all the metal chlorides pass into solution."

A beautiful process of substitution is then described, the gold and silver being precipitated with metallic copper, the copper precipitated with metallic iron, the iron and manganese are reoxidized with chlorine gas and precipitated with zinc oxide, the calcium chloride is converted into calcium sulphate with zinc oxide in the presence of sulphur dioxide, and finally the solution is evaporated to dryness and the zinc recovered by fusion and electrolysis.

The molten zinc is recovered, and the chlorine is peacefully led back to the tube mill.

Thus we have a complete cycle of reactions which delight the soul of the professor and student alike. The chemistry is perfection itself; the chlorides without exception have a much higher heat of formation than the corresponding sulphide, and the substitution process dovetails like a set of child's blocks.

This is my understanding of the Malm process.

The Malm process will not decompose minerals other than sulphides, since the oxides, carbonates and silicates have higher heats of formation than the respective chlorides. Naturally some of the chlorine will in one way or another decompose a small quantity of water, forming hydrochloric acid, and some of the sulphur will be oxidized to sulphuric acid, but the action of these acids is not contemplated in the process as described.

Assuming that the most favorable conditions can be maintained, the extraction as claimed is difficult. Those who have worked with large quantities of chlorine gas and solutions containing chlorine will appreciate that the difficulties are almost insurmountable. There are but few containers adapted to mill work which will easily hold solutions strong in chlorine and at the same time permit the necessary agitation. Also one would not have an unlimited choice of filtering media. It is well enough to say that a filter press of suitable design may be used, but it is a more difficult thing to tell what the suitable material is. This applies to tanks and agitators as well.

The substitution reactions are not quantitative in a commercial way. It is always necessary to have an excess of precipitant in solution. For example, take barium sulphate, one of the most insoluble compounds met with in ordinary work. Try to precipitate all of the barium out of a solution with the theoretical quantity of sulphuric acid. It takes 24 hours for this reaction to take place completely, and then under favorable conditions of excess and temperature.

Assuming one has sufficient tank capacity to hold a thousand pounds of lead chloride in solution, the precipitation of the lead completely with metallic zinc will take time and more time. Also the zinc is going into solution at a very rapid rate, regardless of the lead.

Consider the laboratory precipitation of iron with zinc oxide. The conditions must be delicately adjusted, and a large excess of the precipitant must be added.

There is no magic in large operations which changes these things fundamentally. Time, concentration, heat, and equilibrium must be taken into account in the mill as well as in the laboratory.

Given unlimited time, unlimited apparatus, ideal materials, all of the reactions will take place, each in its turn and according to the chemical laws governing each case. It has yet to be demonstrated that the reactions as claimed will take place in an ordinary plant where operations are continuous and concurrent, where ordinary human beings are a function of operation, and where expensive and fragile apparatus must be used in handling large quantities of very low grade solutions and pulps.

The mainspring of the entire system, the electrolytic decomposition of zinc chloride is in itself a delicate operation. If the production of zinc were as easy as one might be led to believe from a description of this process, no other known process for the recovery of this unhappy element could compete with the electrolytic process. The ease with which zinc is obtained in the Malm process will be referred to later.

I probably shall not convince Mr. Malm that the process is inoperative, but I have stated my reasons specifically above.

To quote further from Mr. Wolf: "From 60 to 70 per cent of the cost of operating this process is for electric power. Direct current at relatively low pressure is used for the electrolytic work. The consumption of power varies with the metal contents of the ore. In practice an actual recovery has been made of 14.2 to 14.4 pounds of zinc per horse-power day."

The theoretical quantity of zinc deposited per horse-power day at 3.5 volts (the voltage specifically stated) is:

$$\frac{746 \times 24 \times 3600 \times 32.7}{3.5 \times 96{,}540 \times 453.5} = 13.8$$

The electrical efficiency of the process is therefore

$$\frac{14.3}{13.8} = 103.5 \text{ per cent.}$$

The heat required for the operation is doubtless derived from the calcium sulphate.

The recovery is stated to be as follows:

| | |
|---|---|
| Gold | 90 % |
| Silver | 91.6% |
| Lead | 97.4% |
| Copper | 99.3% |
| Zinc | 94.2% |

The value of the above products taken from one ton of ore is said to be $23.58. The total cost, including mining, freight, selling and overhead charges, as well as a royalty of 85 cents per ton, is given as $13.57, of which the "entire cost of treatment" per ton is $5.32.

On the average, 65 per cent of this $5.32 was for current; or the entire cost of grinding, chloridizing, decanting, heating, filtering, drying and bottling was $1.86 per ton.

It will be noted that for every pound of metal recovered, at least one pound of zinc must be plated out. To be conservative one should say a pound and a half of zinc to allow for an excess of the precipitant in each case. If this is true (it is an assumption on my part, and not a statement of the writers referred to) we see 414 pounds of zinc recovered per ton of ore treated at a cost for electrical energy of $3.46. One may be sure that there is no half-cent-per-kilowatt-hour rate in Colorado. It is nearer two cents.

This freak list is not complete without the analysis of the ore. The crude ore assayed as follows:

| | |
|---|---|
| Gold | 0.18 oz. per ton |
| Silver | 13.97 " " " |
| Lead | 4.78% |
| Copper | 0.68% |
| Zinc | 9.00% |

It is a remarkable ore which can be obtained for treatment in quantities of 15 tons per day and contains no silica, lime, iron, magnesia or arsenic. These should have been mentioned, since every pound of iron and lime which are chloridized must be disposed of at a heavy expense of zinc.

It is stated that the average profit per ton was $10.00. This means nothing short of $150 per day, or $45,000 per year of 300 days. This is 10 per cent net income or close to half a million dollars. Half a million dollars would put up a fair-sized plant, so Mr. Malm has only himself to blame if he is still unable to complete his Georgetown mill.

Therefore I am convinced that the statements in the references are both incorrect and absurd.

As to the calcium sulphate proposition, it was stated at the meeting above mentioned that the calcium sulphate was causing considerable difficulty. It is stated in one of the articles that calcium sulphate is precipitated by zinc oxide and sulphur dioxide. It is a matter of common knowledge that mill solutions retain relatively large quantities of calcium sulphate, and upon evaporating these solutions the material will certainly appear in the residue.

It now appears that Mr. Malm has either greatly modified his process or developed an entirely new one. Of this I freely confess to know but little. It is to be hoped that this new process will come from under cover so that it may be intelligently discussed, if Mr. Malm desires such a procedure. I do not believe there is a metallurgist in the world who would not be pleased at the ultimate success of the dry chlorination project; and Mr. Malm is deserving of great praise, and substantial reward, should he succeed in making his dream come true. The problems to be solved are as numerous as they are formidable. That many of them have been overcome I believe.

Until such a time as Mr. Malm gives us an equally detailed statement of his present process his previous utterances should stand, and we must base our opinions upon the information he has given us. It remains for Mr. Malm to state specifically and sincerely how he can recover the values from complex Colorado ores at the exceptionally low figure of two and one-half cents per pound.

Warren F. Bleecker.

*Canonsburg, Pa.*

## The Western Metallurgical Field

### Gold Mining and Milling in Georgia

Those who have investigated the history of gold mining in America are inclined to believe that the origin of the industry can be traced to early discoveries and operations in the southern Appalachians. In any event, gold has been produced in Georgia since 1829, for which year the output was officially noticed in the U. S. Mint returns. In 1838 the government opened a mint at Dahlonega and continued coinage there until 1861. This mint coined over $6,000,000 in gold.

At the December meeting of the Colorado Scientific Society, Mr. A. J. Hoskin presented the results of his experience with gold mining and milling in Georgia, giving many details of historical discoveries and early operations, and reviewing the present status of the industry. The rock formations containing the valuable ore deposits are all metamorphosed. The original sedimentaries were chiefly sandstones and slates; but oxidation has been constant, and the original rocks have decomposed in place, giving rise to a condition peculiar to this region, and affecting the methods of mining and milling. The term "saprolite" (rotten rock) has been coined to describe the ore. It is soft and friable, and disintegrates readily in water.

The fineness or purity of Georgia gold is very high, varying from 950 to 980, being wholly free from copper and alloyed with silver only. In size the gold ranges from dust to large nuggets. The small particles of gold are difficult to recover in milling, as they do not readily amalagamate. Some of the difficulty in amalgamation is attributed to nature of the gangue rather than to the quality of the metal.

The mining methods adopted are peculiar to the region, and consist generally in hydraulicking or in dry pick-and-shovel work with subsequent sluicing of the loosened mass from the open cut. The milling process would be deemed inefficient in comparison with practice in the West. Too many opportunities exist for loss of gold. The first part of the process consists in what is known locally as "reducing," meaning thereby a decrease or reduction in the bulk of the ore sent to the mill. This is accomplished by sluicing the ore from the open cut to the mill. During its travel through the sluice the ore is disintegrated, so that on arriving at the stamp mill much of the material will pass a screen of ½-in. or ¼-in. mesh. The Georgian miner assumes that only the coarse portion is worth treatment by amalgamation in the mill, for the gold in the disintegrated portion is supposed to have been recovered in the sluice. Hence the portion passing the screen is run to waste. It would seem almost certain that much gold must be lost in the fine particles that pass the screen, but such is the custom of the local miner; he recovers some gold in sluices, being that part of the metal which has been liberated by the disintegration of the ore, and then treats the coarse ore by stamp-amalgamation to make an additional recovery.

The stamp mills have been evolved to suit local conditions. The stamps are light, weighing from 300 to 450 pounds each. They are run with a low drop, about 95 per minute, and are fed by hand. The plates are silvered copper, but owing to the poor treatment given the plates by the millmen the results are not all that could be desired. The plates are kept too hard or dry, and the millman apparently is averse to using enough mercury to give a proper surface for good amalgamation. This makes cleaning-up a difficult matter, and consequently leads to another bad practice, viz., the use of sharp putty knives in scraping the plates. Knives have always been used to detach the dense deposits from the plates—a practice which might be tolerated with cheap copper plates, but which is prohibitive with expensive silvered plates.

Sulphide ores are found in Georgia, but the miner has a strong aversion to them on account of the fact that they blacken the plates. Mr. Hoskin found that the cause of this lies in the extreme acidity of the ore. Not only does the sulphuric acid foul copper plates, but it rapidly destroys silvered plates.

The general grade of Georgian gold ore is low, averaging about $2 per ton. Extraction percentage is low, being about 50 per cent.; but even with the low-grade ore and low extraction, a profit can be made, owing largely to the cheapness of operation. The Georgia gold fields are nearly dormant at the present time, but are beginning to attract the attention of modern metallurgists, and there is a growing belief that greater activity will be seen within the next few years.

### Concentration of Old Tailings

A novel milling proposition has been undertaken in Colorado by Messrs. Otto Mears and A. R. Wilfley, having for its object the recovery of tailings from a mountain lake and their reconcentration. The Silver Lake mine at Silverton, Colorado, is one of the famous properties of the San Juan region. Like most San Juan mines, the Silver Lake is high in the mountains, being at an altitude of over 13,000 feet. The first mill erected for the concentration of the ore was located at the mine, and discharged its tailings into Silver Lake. The quantity of the material thus accumulated is estimated at about 500,000 tons. This was before the advent of the modern concentrating machinery, and the tailings are probably much richer than would be tolerated under modern conditions.

Some time ago the gentlemen above mentioned projected a plan for the recovery and reconcentration of these tailings, and ultimately began work on a plan which is expected to yield a considerable profit. The tailings are to be pumped from the lake bed and flumed a distance of several miles, being finally delivered at a new mill erected on the Animas river, at an altitude of about 9000 feet. In the new plant there will be concentrating machinery adapted to the treatment of the material. Wilfley multiple-deck tilting slime concentrators will be a feature of the equipment. The capacity of the plant will be over 500 tons per day. It is expected that the average value of the mill feed will be $3 per ton, and a profit of over $1 per ton is anticipated. Owing to the severity of the winter season in the San Juan, it will be possible to operate this new tailings mill only in the summer.

### International Engineering Congress

One of the features of the Panama-Pacific International Exposition in San Francisco, in 1915, will be an International Engineering Congress, embracing all branches of the engineering profession. The date has been set for the week of September 20-25, 1915, which probably is far enough in the future to enable all interested engineers to lay their plans to attend. It is the purpose and object of the congress to gather together engineers from all civilized countries, and offer opportunities for professional and social intercourse. The reading and discussion of papers will be an important feature of the meetings, and the publication of these papers and discussions in suitable volumes will form a permanent record of the transactions. A tentative division of the general engineering field into eleven sections, and the proposed publication of ten volumes of papers, one for each important division, form part of the preliminary arrangements now under way. Of special interest to our readers are the sections devoted to mining engineering and metallurgy, electrical engineering and mechanical engineering. The fee for general membership, including a single volume of transactions will be $5. The committee of management is now seeking to get in touch with all engineers who may be interested, and further information can be obtained by communicating with the secretary, W. A. Cattell, Foxcroft Bldg., San Francisco, Cal.

### New Copper Smelter for Arizona

The International S. & R. Co., now operating a copper and lead smelter at Tooele, Utah, has commenced construction of a new copper smelter near Miami, Ariz. This plant is being erected for the treatment of the concentrates that will soon be forthcoming from the new mill of the Inspiration Company. It is not unlikely, also, that an arrangement will be made whereby the concentrates of the Miami mill, now being sent under contract to Cananea, Mexico, will ultimately be treated by the new smelter. The plant will consist of three modern reverberatory furnaces, possibly one blast furnace and a complement of converters. Considering the immense amount of construction work now under way on copper mills and smelters in Arizona, the addition of a new plant will make this state the most active among Western copper producing states. Needless to say the new plant will be a model of its kind, and unsurpassed by any in the country.

### Company Reports

The fifth annual report of **Stratton's Independence, Ltd.**, has just been issued, covering operations to June 30, 1913. During the period under review the mill treated 104,111 tons of dump ore and 25,999 tons of mine ore, totaling 130,110 tons. The average grade of the ore was 0.1538 oz. gold per ton. The total gold content of ore treated was 20,013 oz. gold, and the recovery was 15,707 oz., or 78.48 per cent. The recovery in concentrates was 34.43 per cent. and in cyanide bullion 44.05 per cent. The percentage extraction is higher than for several years previous. The percentages of recovery from concentrates and bullion are practically reversed from those reported for previous years. Two grades of concentrates are produced; the first grade averaged 4.118 oz. gold per ton, and the second 1.847 oz. All concentrates were sold to smelters. The cost of milling was $1.32 per ton, divided as follows: Coarse crushing and sorting, 17 cents per ton; fine crushing, concentrating and treating concentrate, 52 cents; cyaniding and special chemicals, 50 cents; miscellaneous, 13 cents. The cost of mining dump ore was 12 cents per ton, making a total cost of $1.44 per ton. The average tonnage milled for the fiscal year was 10,842 tons per month. The managers of the property expect to improve results this year.

The **Messina (Transvaal) Development Co., Ltd.**, operating copper mines and reduction works in South Africa, has issued a report for the quarter ended September 30, 1913. This company is one on which Camp Bird, Ltd., holds option for a large number of shares. The first reverberatory smelting furnace was started last July and the second furnace in August. A small calcining furnace was completed and started in September. Two additional reverberatory furnaces are to be added to the equipment and a mechanical roasting furnace also will be built. The report shows that during the quarter the mill produced 1207 tons of 44 per cent. copper concentrates and 918 tons of 8 per cent. middlings. The smelting plant produced during the two months of operation in the quarter 134 tons of 50 per cent. copper matte. This company is just coming into the producing stage after twelve years of development work. A railroad is practically completed to the property and operations are expected to go forward much faster from this time on.

## The Iron and Steel Market

At the close of December a slight improvement is noticeable in the general tone of the iron and steel markets. By the close of November the curve of descending prices in both pig-iron and steel products was trending around to the horizontal and during December the trend has been still more marked. The concavity of the curve is clearly discernible and while this fact is not conclusive as to the future course of the market it is at least a strong indication, for iron and steel prices generally move in great swings.

Prices are not as low, by about 50 cents a ton in pig iron and about $2 a ton in unfinished and finished steel, as they were two years ago when the market made its great descent, to the lowest level since 1904 in pig iron and the lowest level in finished steel since the early part of 1899. It is claimed, however, that the cost of production has meanwhile increased, and that furthermore producers are firmly set against permitting the market to reach a profitless level. Curiously enough, the reduction in the tariff is mentioned as one cause of this resistance to declines. It is suggested that in the past producers were able to average high and low prices, but since the reduced tariff now precludes high prices being attained, sellers must be careful not to allow very low prices to be attained at all. Probably there is something in the argument, for with the chance of importing material before then, it would be more difficult to stampede buyers into purchasing on a rising market.

In the fore part of December steel mills operations were at about the same rate as at the close of November, about 50 per cent of full capacity, but with extensive closing of plants over the holidays the month's production and shipments have probably not been much above 40 per cent of capacity. There is clear prospect of heavier tonnage in January, this probably to be followed by continued improvement in following months.

Despite the unfavorable sentiment that has been so prevalent, close analysis fails to disclose anything radically wrong with the country. Thus far the tariff reduction has shown itself far less dangerous than was predicted. October, the first month of the new tariff, which became law on the night of October 3, showed inconsequential iron and steel imports, practically no increase over August and September, and a great reduction as compared with the earlier months of the year, while the country's general balance of trade was the greatest for any month in history. The currency question is settled and criticism of the new arrangement is likely to subside. The trust question is next in order for discussion at Washington, and the discussion can hardly prove as disturbing an element as has been the uncertainty of business men as to what they could do and what they could not do. In nearly all quarters it has been agreed that settlement in almost any fashion would be better than the uncertainty.

### Pig Iron

The market was a dull and dragging one in the fore part of December, but just after the middle of the month it developed that two important interests, the International Harvester Company and the American Steel Foundries, had made important purchases, involving 50,000 to 75,000 tons, for forward delivery, this constituting the first forward business of any magnitude closed since midsummer, and it is not improbable that after the turn of the year the pig iron markets will feel some stimulus in consequence. Prices are very low and production appears to have been restricted to the full extent required by reduced consumption, if indeed the restriction has not gone too far. Declines since last report have been light. Quotations are: No. 2 foundry, f.o.b. Birmingham, $10.50 to $11; No. 2 X foundry, delivered, Philadelphia, $15 to $15.25; No. 2 X, f.o.b. Buffalo furnaces, $12.75 to $13; No. 2 foundry, delivered, Cleveland, $13.50; No. 2 foundry, f.o.b. Chicago furnaces, $14; at Valley furnaces (90 cents higher delivered Pittsburgh), Bessemer, $15; basic, $12.75; malleable, $13.50; No. 2 foundry, $13.50; forge, $13.15. Ferromanganese was reduced $3 a ton early in December and is quotable at $47, f.o.b. Baltimore, for English or German, prompt or forward.

### Steel

December settlements of prices on monthly adjustment contracts were on the basis of $20 for billets and $21 for sheet bars, at maker's mill, Pittsburgh or Youngstown. In some instances slight concessions are understood to have been made, but these figures closely represent the quotable market. Rods have softened to $25.50, Pittsburgh. The market is stronger in tone in that mills refuse to sell billets or sheet bars for second quarter at prevailing prices, and even for first quarter are not always willing to sell Bessemer at the same level as open-hearth. They claim the production cost is higher for Bessemer. Frequently open-hearth steel has commanded a premium over Bessemer, and the relation probably depends more on situation as to demand and supply than on the situation as to cost of production.

### Finished Steel

Since last report plates, shapes and bars have declined $1 a ton, the declines occurring early in December, since when the market has been stationary. Quotations now named can occasionally be shaded in the case of large tonnages for prompt shipment, the mills being rather averse to loading up with contract tonnage even at the full quoted prices. Sheets and wire products have also declined $1 a ton, and are not overly firm, for prompt shipment at the new quotations. Prices are f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard section, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.20c.

Shapes, 1.25c.

Steel bars, 1.20c., base.

Iron bars, 1.35c. Pittsburgh, 1.10c. Chicago, $1.22\frac{1}{2}$c. Philadelphia.

Wire nails, $1.55 per keg, base; plain wire, 1.35c., base.

Sheets, blue annealed, 10 gage, 1.50c.; black, 28 gage, 1.90c.; galvanized, 28 gage, 2.90c.; painted corrugated, 28 gage, 2.10c.; galvanized corrugated, 2.95c.

Merchant steel pipe, $\frac{3}{4}$ to 3-in., 80 per cent off list.

Steel boiler tubes, $3\frac{1}{2}$ to $4\frac{1}{2}$-in., 69 per cent off list.

Standard railroad spikes, 1.50c. Pittsburgh, 1.55c. Chicago.

Button head structural rivets, 1.75c.; cone head boiler rivets, 1.85c.

Cold rolled shafting, 62 per cent off list.

**Cyanidation in the Mercur District, Utah,** is the title of a pamphlet recently issued by the *Salt Lake Mining Review*, giving a history of metallurgical operations in a famous mining district, where the modern vacuum filter was invented. The pamphlet contains many illustrations of milling operations.

### The Non-Ferrous Metal Market

The metal markets generally have been dull, and prices have had a steady tendency downward since our last report. Stocks of metals have accumulated, and purchasers have not been active in spite of lower prices. This fact has led to the belief that even a lower level will have to be reached before buyers will again enter the market.

**Copper.**—About the middle of December prices became practically nominal and the producers sold metal for what they could get. Some foreign business has been done, but the domestic market has been dull. Lake copper is quoted nominally at 14¾c. to 15c., this being practically the price asked by Calumet & Hecla, which is the only Lake producer which has much metal for sale. Electrolytic is quoted at 14.05c. to 14.15c.

**Tin.**—The domestic market has reflected the weak condition of the London market and little business has been done. December tin is lower, being quoted at 37½c.

**Lead.**—Since our last report the leading producer has made two cuts in the price for this metal, and conditions are being reached where some mines will not be able to produce at a profit. New York lead is quoted at 4c. per lb., and St. Louis at 3.85c.

**Spelter.**—This market has been decidedly weak and prices have suffered a sharp decline. Stocks of spelter are accumulating, but buyers remain out of the market. It is felt, however, that prices will not go lower, as buyers are not well covered, and must soon enter the market. New York spelter is quoted at 5.10c. to 5.15c., and St. Louis at 4.95c. to 5c.

**Other Metals.**—The aluminium market is quiet and only a moderate business is done. Prices are 18¾c. to 19¼c. for No. 1 ingots. A similar situation prevails in the antimony market; prices are inclined to be weak, and range from 6c. to 7⅝c. for various brands. The quicksilver market is more steady with fair prices prevailing. New York quotes $39 to $40 per flask of 75 lb., and San Francisco $39.

---

### Symposium of Papers on the Power Problem in the Electrolytic Deposition of Metals

**Joint Meeting of the American Institute of Electrical Engineers and the New York Section of the American Electrochemical Society**

The next meeting of the New York Section of the American Electrochemical Society will be a joint one with the American Institute of Electrical Engineers and the New York Section of the American Society of Mechanical Engineers, at 8:15 p. m., Friday, Jan. 9, 1914, in the auditorium of the Engineering Societies Building, 29 West Thirty-ninth Street, New York City. Dr. C. O. Mailloux will preside. After the meeting members of the section will be the guests of the A. I. E. E. at a smoker to be held in the rooms of the Institute.

The subject for the evening is "The Power Problem in the Electrolytic Deposition of Metals," and the program is as follows:

*The Limitations of the Problem.* By LAWRENCE ADDICKS, Supt. United States Metals Refining Company. (A brief statement of the conditions imposed by practice in the electrolytic refining of copper as a typical process.)

*The Mechanical Side of the Problem.* By H. E. LONGWELL, Mech. Engineer, Westinghouse Machine Company. (Application of gas and steam for driving generators of the type required.)

*The Electrical Side of the Problem.* By F. D. NEWBURY, Division Engineer, Westinghouse Elec. & Mfg. Company. (Application of various d.c. and a.c.-d.c. apparatus to furnish current of the required dimensions.)

The papers will be illustrated and the discussion should be interesting, as the subject is much broader than the typical case chosen for the formal papers.

---

### Meeting of Secretaries of National Technical Societies

Following a call sent out by W. M. Corse, Secretary of the American Institute of Metals, for a meeting to discuss the question of avoiding conflict of dates in the meetings of national, scientific and engineering societies, representatives of fifteen national societies met in the reception room of the American Institute of Mining Engineers, New York City, on Saturday, December 13, 1913. The following American societies were represented by their Secretaries: American Society of Mechanical Engineers, American Institute of Mining Engineers, American Institute of Electrical Engineers, American Chemical Society, American Electrochemical Society, American Institute of Metals, American Institute of Chemical Engineers, American Society for Testing Materials, National Electric Light Association, American Efficiency Society, American Gas Institute, American Society of Gas Lighting, Franklin Institute; besides these, H. D. Vought represented the Railway Engineers and David H. Browne the Canadian Mining Institute. Secretary Stoughton, of the Mining Engineers, served as chairman and W. M. Corse as secretary *pro tem.*

After a long and spirited discussion of various questions needing adjustment, and which it was thought could best be handled by co-operation between the secretaries of the various national societies, the following committee was appointed to serve *pro tem* as a clearing house for announcing to the societies represented the dates of meetings which have been already fixed for 1914, and announcing others as they may be hereafter fixed; also to confer with a similar committee of the Railway Association Secretaries to see whether the two committees could not work in unison, or adopt some uniform plan for future regulation of these questions: W. M. Corse, *chairman;* J. C. Olsen, F. L. Hutchinson, C. W. Rice; Bradley Stoughton, *secretary.* This committee will hold a meeting with the other committee mentioned in the rooms of the American Railway Association, Underwood Building, New York City, on January 10 next at 11 a. m.

It is to be confidently hoped that this move will either stop or reduce to an unavoidable minimum the conflicts of dates in meetings of national societies, which have certainly been annoyingly frequent during 1913.

---

### The Faraday Society

The annual general meeting of the Faraday Society was held on Wednesday, November 26, 1913, at the Institution of Electrical Engineers, in London. The following officers and council were elected to serve for the year 1913-14:

*President*—Sir Robert Hadfield, F.R.S.

*Vice-Presidents*—G. T. Beilby, F.R.S.; Professor K. Birkeland, W. R. Bousfield, K.C.; Professor Bertram Hopkinson, F.R.S.; Professor A. K. Huntington, T. Martin Lowry, D.Sc.; Alexander Siemens, M.Inst.C.E.

*Treasurer*—F. Mollwo Perkin, Ph.D.

*Council*—R. Belfield, Dr. H. Borns, W. R. Cooper, Professor F. G. Donnan, F.R.S.; Emil Hatschek, Dr. R. S. Hutton, Professor Alfred W. Porter, F.R.S.; E. H. Rayner, Dr. R. Seligman, Maurice Solomon.

The seventieth ordinary meeting of the Faraday Society was subsequently held.

A paper communicated by Mr. **Ernest Vanstone** (Birmingham) on *The Electrical Conductivities of Sodium Amalgams* was read in abstract by the secretary.

Continuing the physico-chemical investigation of sodium amalgams the author has determined the electrical conductivities of about twenty alloys. The composition of the alloys varied from 100 atoms per cent. sodium to 54 atoms per cent.

In order to obtain a sufficiently long thread of metal for resistance measurements the alloys were drawn up into a capillary spiral 1 mm diameter and about a meter in length when unwound; platinum terminals were sealed in the spiral at points about a meter apart.

The resistances were measured by a compensation method. Great difficulty was experienced in obtaining a continuous uniform thread.

The conductivity-concentration curve shows discontinuities at concentrations of 15 and 21 per cent mercury and a flat minimum of 35 per cent.

The present paper is a preliminary to a more extensive investigation.

A paper on *The Influence of a Second Solute on the Solubility of Ortho-phthalic Acid*, by Dr. **A. C. Rivett** and Mr. **E. I. Rosenblum**, was read by Dr. Rivett.

The authors have investigated the solubility of orthophthalic acid in solutions of various concentrations of some twenty-six solutes, including twenty-one salts. Their object has been to collect a considerable amount of information which will be available for comparison with similar work on the influence of salts on such other properties of a second solute as diffusion, lowering of freezing point of solvent and reaction velocity.

The form of curve connecting solubility and salt concentration is of the usual type, showing an initial rise followed by a more or less sharp fall. Double decomposition and perhaps increased dissociation of the acid will be partly responsible for the initial rise. In the later part of the curve these become relatively of less importance and at a sufficiently high concentration will be slight compared with the decrease due to so-called neutral salt action. If the curve in its later part be extrapolated to cut the solubility axis at $S_o$, then $S_o$ represents what the concentration of phthalic acid would be in pure water if those conditions alone ruled in approaching it which determine the later part of the curve. Such extrapolation is possible only where the initial rise is very slight. If now the alteration of saturation concentration of the acid depend upon the ions and molecules present, in whatever way these may act, the relation should hold:

$$S = S_o \left\{ 1 + k\alpha C + k' (1 - \alpha) C \right\}$$

where S is solubility and $\alpha$ is degree of dissociation of the salt at concentration C; $k$ and $k'$ are ionic and molecular constants, respectively, of so-called "neutral salt action."

The authors show that it is possible, by choosing suitable values for $k$ and $k'$, to reproduce the solubilities of phthalic acid in presence of LiCl, NaCl, KCl, $MgCl_2$, $CaCl_2$, $BaCl_2$, HCl, KBr, KI, and NaNO , up to concentrations of about 1-molar normal, practically within the limit of experimental error. The calculations involve the usual assumptions as to the possibility of obtaining measures of the degrees of dissociation of salts.

Dr. T. Martin Lowry drew attention to the analogous case of the diminution in solubility of gases in water containing salts in solution.

Dr. E. K. Rideal said that it would have been better to experiment with a substance whose molecule was more symmetrical than that of orthophtalic acid and which would "hydrate" in as simple a manner as possible.

Mr. R. E. Slade remarked that it would be interesting to know the dissociation constant of ortho-phthalic acid, but the author was unable to give it. If there were not much double decomposition on the hydration theory why did $K_2SO_4$ send up the solubility enormously while $Na_2SO_4$ did not?

**The Chairman** said he would like to be able to compare the authors' curves with those given by another solute. In the case of organic radicles it was fairly certain they had hardly any water molecules associated with them.

**Dr. T. Martin Lowry** showed a series of photographs illustrating the *Formation of an Oxidizable Variety of Nitrogen* by the action of a spark discharge on air at atmospheric pressure. The product has the property of being oxidized by ozone to nitrogen peroxide; but if no ozone is added to the gas the yield of peroxide is very small, the greater part of the oxidizable nitrogen reverting under these conditions to the ordinary form. The absorption spectra, which were used to detect and to estimate the nitrogen peroxide, were of interest as having been taken with the help of a column of gas 64 feet in length.

The Chairman said he believed ozone was only produced by a discharge which followed a highly peaked curve.

Professor Alfred W. Porter, F.R.S., in the course of his remarks, referred to the palmleaf-like figures which form, after development, upon photographic plates after passing a negative discharge over them, and which are only obtained in gases containing *free* nitrogen. The figures seemed to indicate that a very loose molecular, ionic, or atomic aggregate travelled with the discharge and ultimately broke up explosively like shrapnel. The immediate product of the explosion was probably Strutt's nitrogen.

A discussion followed on a paper presented at the previous meeting by **Dr. F. J. Brislee** on *The Density of Aluminium.*

The discussion centered round the author's observation that rolling and otherwise working the metal reduces its density, and his explanation of this as due to a transformation from crystalline to amorphous states.

Dr. R. Seligman remarked on the technical importance of the observation, the worked metal being more prone to corrosion because it was amorphous. He agreed as to the probability of the metal changing its state, which would bring it in line with other metals.

Dr. T. Martin Lowry thought that the decrease of density due to rolling might be within the limits of experimental error.

A note communicated to the previous meeting by **Professor J. W. Richards**, of Lehigh University, U.S.A., on *Overvoltage* led to some discussion.

In his note Professor Richards states that it is an error to regard overvoltage as if it did chemical work and was of the nature of decomposition voltage. He regards it as merely due to surface resistance caused by gas on the electrode, so that the energy absorbed appears as sensible heat. This was tested calorimetrically on a voltaic cell.

Dr. F. J. Brislee in a written communication criticized the author's experiments, which seemed to him to prove nothing with regard to the nature of overvoltage. The balance of evidence, however, favored the view that it is associated with the doing of chemical work followed by the degradation of the chemical energy to heat.

Mr. U. R. Evans opposed the view that over-potential was an irreversible electrodic change, involving waste of energy. It required no special explanation, being merely due to the fact that the formation of bubbles required a considerable degree of supersaturation of the cathode with hydrogen. It was a simple phenomenon, quite analogous to superheating a liquid—itself also a surface tension effect.

# The Effect of Legislation Upon Chemical Industries

## Presidential Address Delivered before the American Institute of Chemical Engineers.

BY T. B. WAGNER

At the end of the eighteenth century an observation was made by Scheele in his laboratory, the results of which have meant more to the prosperity of all peoples inhabiting this planet than any other invention—chemical or otherwise. I am referring to the observation which disclosed the fact that cyanide of potassium is capable of dissolving gold. While this discovery was of much scientific interest at the time, and led Faraday to explain it by an elaborate theory, no industrial application was given to it until about one hundred years later.

In April, 1890, the first plant operating under the McArthur-Forest method for treating ore tailings was started in Johannesburg.

The effect of this process is reflected in a tremendous increase of the world's output of gold; consequently, the cyanide process plays an important part in the monetary system of the world, as the increased gold production effected by it has dispelled the fear that there might not be enough of the precious metal to maintain the gold standard of the civilized nations. The struggle in this country for the maintenance of the gold standard is within the memory of all, but I fear that like in other instances, credit was not given to the chemist for his share in having the gold standard preserved.

The recital of this invention has no immediate bearing upon my subject, except in so far as it goes to prove that the furtherance of civilization and the furtherance of industries depend largely upon underlying conditions, which, in their incipiency, may seem trivial. That is the case with the effect of legislation upon the development of chemical industries. The chemical industries of the world are a little over 100 years old, yet, in point of advancement and financial returns, their success is without a rival. Strange as it may seem, the starting of industrial enterprises is not always due to the chase for the almighty dollar, as is generally and perhaps pardonably assumed, but in many instances it is directly caused by the enactment of laws with more or less restrictive tendencies.

Let us go back to the birth of the chemical industries in the beginning of the last century. Napoleon the First whose fame as a stateman and as a conqueror will stand like a beacon light as long as history shall be written, was at war with England. To crush his rival, this far-sighted statesman conceived the idea that the most effective way of accomplishing his purpose lay in the crippling of England's trade. The Continent naturally was the principal buyer of England's colonial products. Napoleon, therefore, in 1806, issued a ukase, according to which England's colonial products were barred from the Continent, and all trade relations with England were forbidden; any country violating this ukase was apt to find itself involved in war with France. This ukase is known as Napoleon's "colonial blockade."

Among England's most important colonial products was cane sugar, but with the enforcement of the blockade, the Continent found itself unable to obtain this sweetening agent, without which life seems to be less sweet indeed. The price of sugar rose enormously and an impetus was thus given to the exploitation of the discovery of Margraf, made in 1747, that the ordinary garden beet root contained considerable quantities of sugar, identical with that found in the sugar cane. The first factory was built in Germany in 1801. Since then this industry has had a marvelous growth, and the present production of sugar from this source exceeds that from cane. The world's production of sugar today is 18,500,000 tons, of which 9,000,000 tons are obtained from the sugar cane, and 9,500,000 tons from the sugar beet.

Of the latter only a little over 600,000 tons are produced in this country, the factories engaged in its manufacture numbering seventy-two.

Incidentally I might mention that while at the beginning of the industry about 20 tons of beets were required for the production of 1 ton of sugar, the same amount of sugar is now obtained from only 7 tons of beets.

It is also worthy of mention here that all of the potassium contained in the sugar beets and fully 65 per cent of their contents of nitrogen are recovered from the molasses and utilized over again. What effect the latest legislation, the new tariff, will have upon the industry in this country, whether it will prove that it has outgrown the state of an infant industry, or whether it still requires the friendly and substantial support of a high protective tariff—that the future will demonstrate within a few years.

Coincident with the establishment of the beet sugar industry was that of another industry which was destined to play an important part in the economic conditions of this country and Germany, viz., the production of grape sugar from starch. The success of this new industry, it may be rightly assumed, is also attributable to Napoleon's exclusion of England's cane sugar from the Continent. The conversion of starch into a reducing sugar, by means of a dilute acid and heat, was discovered in 1811 by Kirchhoff, a teacher at the Imperial Academy of Sciences at St. Petersburg. and the first factory was built in Germany in the same year by the Grand Duke of Saxe-Weimar, at the instance of Professor Doebereiner of the University of Jena, whom you will remember as the inventor of the first "hydrogen lamp."

Bearing in mind the present magnitude of this industry, it is interesting to read of the financing of this pioneer factory in Germany.

I quote from a letter of the Grand Duke to Professor Doebereiner:

"The subscription is assured; my wife and I, my son and his wife are the four stockholders, each contributing 100 talers. I shall advance the capital of 400 talers, which is to bear interest at 5 per cent, and shall turn this over to you; you may then proceed immediately to start the plant. I shall deed my shares to you; I wish you every success and I am convinced that you will proceed carefully. As regards the concession, I believe it can be arranged that it shall be granted for a period of years, however, it must not include the home production of syrup for home use. I intend coming to Jena this week; I shall then bring the money with me and we may discuss further details. I have looked up the manufacture of sulphuric acid in Chaptal & Klaproth. It seems to require a large capital, however, to build the lead chamber."

From this small beginning the industry has grown into one of vast proportions, the yearly production in Germany being 120,000,000 lb., and whereas, at the start, only grape sugar and syrup were produced, and the potato was the only form of raw material, at present by far the largest amount is produced from Indian corn and the number of different commercial commodities produced from the latter reaches almost one hundred. The industry consumes in this country about 50,000,000 bu. of corn annually, or practically one-sixth of all the corn which reaches the markets.

These figures must not be interpreted as meaning a steady and unhampered growth of the industry. On the contrary, if all the legislation which was enacted had had the effect anticipated at the time of enactment, the industry would not have survived these attacks.

For instance, in various states laws were passed putting glucose and grape sugar in the same category as poisons and prohibiting their use in food products. Only last year attempts were made in the legislatures of two states to exclude glucose from use in confectionery, although it is conceded that its use results in a better grade of candy and that certain goods cannot be made without it.

Again when it was discovered by Dr. Ludwig Gall that grape sugar lends itself admirably to the improving of wines, in which the amount of sugar produced by nature is deficient on account of adverse climatic conditions. this method of ameliorating wines, which has come to be known as "Gallizing," was hailed in Germany as one of the most important discoveries, affecting and improving the economic conditions of the provinces in which the wines were produced. Owing to the large demand which Dr. Gall's discovery created for this sugar, it contributed materially to the growth of the industry. Yet we find that only a few years ago conditions were reversed by legislative action and great restrictions were placed upon the use of this sugar in the amelioration of wines.

In this country the controversy over the use of sugar in wines, only a few months ago, almost caused the failure of the new tariff act. Our domestic wine industry is centered principally in the State of California one one side, and the States of Ohio and Missouri on the other. California produces grapes rich in sugar, whereas even the best grapes produced in Ohio are deficient in sugar to such an extent as to produce a wine so low in alcohol as to be almost unmerchantable. The Ohio and Missouri wine producers therefore resorted to "Gallizing" ever since the industry was started in their states, about 60 years ago. Their ameliorated wines are said to be as good as any produced in California, yet the wine producers of that State tried to create the impression in Congress and elsewhere that California wines were the only pure wines, whereas those produced in Ohio and Missouri were adulterated because of the addition of sugar.

In the production of sweet wines it becomes necessary to "fortify" the wines with brandy, and the California people succeeded in having an act passed by Congress in 1890 which permitted them to use brandy without paying the spirit tax of $1.10. It is said that since the passage of this act the amount of money saved to the California interests was not less than $63,000,000.

To retaliate against California, the Ohio and Missouri interests appeared before Congress when the Underwood tariff bill was under consideration. One section of the tariff act deals with the income derived from internal revenue, and here the Eastern interests saw their opportunity and introduced a bill which would take from the California wine producers the privilege of using tax-free brandy. It would compel them to pay into the United States Treasury annually something like $8,000,000.

The California interests answered in kind by introducing a bill placing a tax of 25 cents per gallon upon all wines produced in the territory east of the Rocky Mountains, which, if enacted into law, would mean the annihilation of the industry in that territory. This in turn would injure the grape sugar industry, as it would curtail the consumption of grape sugar.

Further consideration of the tariff bill came to a standstill, as this so-called wine clause proved the stumbling block, and no headway was made until the entire wine clause was eliminated for the time being—Congress agreeing to give it its attention during the regular session.

I cite these cases to show the influence of legislation, even though indirect, upon the development of a chemical industry. What is one's loss is another's gain. For instance, the loss of the sugar business to England meant the birth of two important new industries and these in turn influenced the development of other branches of the chemical industries. It is but fair to state that the chemical industries in general owe a great deal to the beet sugar industry. Looking over the list of early chemists and chemical engineers, who have distinguished themselves in the chemical industries, we find that most of them had their start in a beet sugar factory—likewise many successful works managers, for it was in this industry that the first complicated machinery was installed. The modern evaporating devices as well as the separation of solids from liquids by centrifugal force, had their inception in beet sugar works.

I cannot leave this chapter without mentioning another instance bearing upon the beneficial, although unlooked for, results of restrictive legislation. A number of years ago a law was enacted in one of the wine-producing countries abroad with reference to wines made from the residue of the pressings of the grapes, the so-called "pomace" wines. These wines were introduced by Petiot, a French wine merchant, and were produced from Bordeaux wines by adding a sugar solution to the residue from the first must and fermenting a second time. The alcohol generated thereby dissolved coloring substances, as well as tannin and the flavoring principles, the "bouquet." This treatment is known as "petiotizing" and is applied to Bordeaux wines four or five times in succession.

Much sophistication was practiced—the pomace wines being sold frequently as natural wines. The Government recognized the legitimacy of the "pomace" wine business, but it wanted these wines to be sold for what they were and did not want them sold to the public under a misleading name. The wines were supposed to be sold as "pomace wines," and to enable the Government officers to distinguish them from "natural" wines, and to identify a pomace wine, the law provided that these wines must receive, before marketing, the addition of a small amount of phenolphthalein. The inspector would examine the wines by adding a few drops of an alkaline solution which, of course, would turn the color red. If the color of a "natural" wine turned red it was *prima facie* evidence that a pomace wine had been substituted.

After this law had been in effect for about a year it was observed that peasants living in the district where these pomace wines were produced and consuming rather large quantities of these wines developed what was then considered a disease and which assumed the proportions of an epidemic. The Government dispatched its medical officers to make a thorough investigation and subsequently they reported that they believed phenolphthalein to be the cause of the trouble. Thereupon clinical tests were instituted and the fact established that phenolphthalein was a most effective cathartic. While heretofore phenolphthalein was used primarily in the laboratories as an indicator, it now assumed an important position among our therapeutic chemicals and is at present manufactured in very large quantities.

Before leaving the subject of sugars, I must not omit a reference to saccharine, a substance which has received extensive attention at the hand of legislative bodies. As you know, saccharine was discovered by Dr. Fahlberg, while taking a post graduate course with Professor Ira Remsen at Johns Hopkins University. It was more or less an accidental discovery, as Dr. Fahlberg's work was in the direction of coal tar derivatives from a purely scientific point of view. The manufacture of this new sweetening agent was started in Germany and a new industry created which grew in importance so that it was eventually considered a menace to the beet sugar industry of the Continent.

The latter, of course, is of greater importance to Continental countries, from an economic point of view, and the new rival of beet sugar was therefore discriminated against by laws which prohibited the use of this sweetening substance as a substitute for sugar, permitting its employment solely for medical purposes, the Governments of Germany and Italy going so far as to prohibit the manufacture of the article itself. It was not prohibited because the article was injurious to health, but simply because of economic considerations. The importation into Germany being prohibited, it is interesting to note the accounts in the trade papers of the vast amount of smuggling from Switzerland into Germany.

Incidentally this shows that notwithstanding the prohibition of saccharine in food, a large demand for it still exists, and I am told that it is used chiefly in the households for sweetening jellies, jams, preserves and similar products in place of the expensive beet sugar, rather than by the manufacturers of such products. I read an account in one of the trade journals recently, according to which it was observed for some time by the Customs authorities that an astonishingly large number of funeral parties crossed the Swiss frontier into the adjoining Grand Duchy of Baden—the explanation given being that the bodies were shipped into Germany in conformity with the wishes of the deceased to be buried in their native land. The number of funeral parties steadily growing in numbers, the Customs authorities finally had their suspicions aroused and ordered a casket to be opened. It was discovered that in place of the supposed corpse, the casket was filled with packages of saccharine!

The most far-reaching legislation ever enacted was that directed against the discharge of sulphurous acid fumes from ore smelters. With the increased output of these smelters, the volume of sulphurous acid discharged into the air became so large as to produce a most destructive effect upon vegetation. Laws were enacted in this country, as well as abroad, to the effect that unless the sulphurous acid fumes could be rendered harmless the operation of these smelters would have to be stopped. The first attempts to convert them into a useful article were in the direction of compressing the gases into liquid sulphurous acid, which was used in the manufacture of glue and gelatine, but the amount of gas recovered from the furnaces grow so enormous that this outlet was not sufficient.

The attempts were then directed to oxidizing the sulphurous acid by means of the oxygen of the air for the production of sulphuric trioxide, following the reaction discovered by Clemens Winkler. These efforts proved extremely successful and works were soon established where $SO_3$ and finally sulphuric acid was generated from the waste sulphurous acid gases. In this manner a new process for manufacturing sulphuric acid was created, the so-called "contact process," which, in the course of time, thoroughly revolutionized a branch of chemical industry, in which the old established chamber process had come to be considered impossible of improvement.

I am particularly pleased to be able to refer in this connection to the splendid work of our fellow member, Mr. J. B. Francis Herreshoff, whose contact process has proved so superior to that of the Badische Anilin and Sodafabrik in point of economy and simplicity of operation that it is now being introduced into Germany.

The utilization of the waste gases from smelters had the effect of producing cheap sulphuric acid in localities where it would have been impossible to produce it by any other method. This had the most beneficial effect upon the development of the fertilizer industry in this country. Our Southern States, principally Florida and Tennessee, furnish today the bulk of the world's requirements of phosphatic rock. Liebig showed us how this insoluble phosphorus could be converted into a soluble form by a treatment with sulphuric acid, and for this purpose alone over 3,000,000 tons of acid are used per year.

The contact process, in turn, was responsible for the successful commercial production of synthetic indigo. The most successful method of producing it is a combination of methods suggested independently of each other, and consists in the following steps:

1. Naphthalene to phthalic acid.
2. Phthalic acid anhydride to phthalic imide.
3. Phthalic imide to anthranilic acid.
4. Anthranilic acid to phenylglycin ortho carbonic acid.

5—Phenylglycin ortho carbonic acid to indigo.

The greatest problem was the production of phthalic acid. Heretofore it has been obtained through the oxidation of naphthalene by chromic acid. The latter, however, was very expensive and this method did not hold out much hope of commercial success. E. Sapper, a chemist engaged in experiments to reduce the cost of production of phthalic acid, conceived a new process of making it by heating naphthalene with highly concentrated fuming sulphuric acid. After years of experimenting a suitable method was found in the discovery of which Accident, the patron saint of the inventor, played an important rôle. It was discovered that the addition of mercury to the solution of naphthalene in fuming sulphuric acid facilitated the reaction and resulted in an almost theoretical yield.

We must bear in mind, however, that the commercial success of synthetic indigo was influenced, to a large extent, by the fact that the $SO_2$ generated by the process of heating naphthalene with sulphuric acid could be reconverted into $SO_3$ by the contact process. Even 10 years ago one single establishment engaged in the manufacture of synthetic indigo reconverted into $SO_3$ 40,000 tons of sulphurous acid per year, obtained in the manufacture of phthalic acid.

Thus we have seen that through the instrumentality of the law, a chemical process was introduced into metallurgical establishments, the contact process was created, a cheap supply of sulphuric acid was secured, which in turn proved a blessing to agricultural interests through the production of a cheap fertilizing material, and finally it made possible the commercial exploitation of one of the finest achievements of scientific effort—the production of synthetic indigo.

Another impetus was given to chemical industries by laws aimed at stopping the contamination and pollution of rivers and other waters. Before the value of by-products was understood by manufacturers, the rivers and waterways in general were used as the most convenient and inexpensive way of removing offal and waste of all kinds from the factory.

It is not difficult to understand the results from such abuse of natural water courses. The communities deriving their supply of drinking water from these sources were especially affected by it; the water, deprived of its natural content of oxygen, caused the death of the fish habitating in these waters and the odor produced by the decomposition of this offal brought much discomfort to the people living within the vicinity of such streams. It was a condition of which the Legislatures were compelled to take cognizance, and the inevitable result was the prohibition of such use.

This legislation proved disastrous to many industries but it proved of the greatest benefit to a far larger number. Among others, it affected beneficially all the industries connected with fermentation and those connected with the manufacture of starch from various raw materials. The materials recovered from the waste of these industries were converted into dry form, serving, in most instances, for the feeding of cattle and live stock. Such feeds are those produced from the starch works, distilleries and breweries, and they rank among the most valuable concentrated feeding stuffs. They are indispensable for the rational feeding of live stock, which, together with wheat, form the principal means of sustenance of mankind. The production in this country of foodstuffs from the manufacture of starch alone amounts to over 300,000 tons per year, and since these foodstuffs sell at approximately $25 a ton, the revenue obtained from this source amounts to $7,500,000 per annum.

In former years it was customary to allow the germs of the corn to go to waste, but today the industry recovers about 75,000,000 lb. of oil per year, which is sold in the markets of the world at about $4,500,000. The corn solubles—the so-called steep water—is now recovered to the extent of 100,000,000 lbs. a year, which is sold also in the world's markets at over $1,000,000. The by-products recovered from distilleries and breweries in this country may be said to be worth about $5,000,000 per year.

One of the most prolific sources of legislation is oleomargarine. Laws have been enacted in many States aimed at the destruction of this industry, as for instance the oleomargarine laws of Pennsylvania and New Hampshire, which required that no oleomargarine should be sold in those States unless it were colored pink. Yet, in spite of these restrictive, if not prohibitive, laws, this industry has prospered, simply because of the underlying merit of the product itself. This is well illustrated by the fact that the receipts of the internal revenue office from the tax on oleomargarine amounted to $1,259,987.65 during the fiscal year ending June 30, 1913.

This subject furnishes a most interesting sidelight on the incongruities of laws. The artificial coloring of natural butter is permitted by a special act of Congress, even though the butter color used at the time of the enactment of this law would not be permitted today under the Federal Food & Drugs Act because of its injurious character.

The artificial coloring of oleomargarine, however, is not permitted, because such practice would make it an imitation of butter. If, however, the producer of oleomargarine is willing to pay a tax of 10 cents per pound, he then acquires the right to put his "fraudulent" product upon the market and the Government becomes his silent partner. Most of the oleomargarine is produced by the packers, but it is only one of a large number of chemical products manufactured by them.

It is only a relatively short time since chemistry has entered the packing houses and it was not entirely a matter of choice that led to the entry of the chemist, but rather stern necessity, for the law had served notice upon the packers that a stop would soon be put to their practice of discharging their enormous putrefactive wastes into creeks and rivers. This could not be accomplished without the aid of the chemist and the chemical engineer.

As a result of their work, the packers produce today not only meats, meat extracts and soups, but they manufacture lard, tallow, stearine and oleomargarine. They also produce soaps, candles and hydrogenated fats; in the manufacture of these products, they recover glycerin as a by-product. From the different parts of the animal, especially from the pancreas, the thyroid and the suprarenal glands, therapeutic agents of great medicinal value are obtained.

From the stomachs of hogs pepsin is produced and the use of the latter has been greatly increased within recent years by the clever discovery of two brother chemists, the Messrs. Wallerstein of this city, that beer of absolute chill-proof quality is obtained by the use of pepsin. The governing thought of their invention lay in the desire to keep those albumenoid substances in colloidal solution which could not be separated during the process of refrigeration; the use of a minute quantity of pepsin makes this possible.

Further by-products of the packing houses are glue and gelatine, both products of great importance, particularly in view of the universal shortage all over the world of glue stock, and the correspondingly high prices prevailing for these products. The bones of the slaughtered animals are charred for the preparation of bone black, which, as you know, is a valuable filtering and refining material. In other departments of the packing plants brushes are made from the bristles of the hogs. The hair is also recovered and the skins and hides go to the tanneries to be converted into leather. What is left is placed on the market as fertilizing materials, as for instance, dried blood and tankage.

Viewing these remarkable results, it is obvious that there is hardly any necessity of further legislation for the disposition of offal from the packing plants.

Other industries directly affected by legislation prohibiting the pollution of streams are the paper and pulp industries. Here, however, the problem of a satisfactory disposition of the objectionable materials offers greater difficulties than in most of the other industries. Some of the waste material is recovered through mechanical separators, but most of it still goes to waste, and this has resulted in the closing by law of a number of plants.

A beginning towards recovery has been made through the Mueller-Kestner process whereby the spent sulfite liquors are neutralized and then concentrated in a vacuum system. The liquid thus obtained is used principally for laying dust on roads in the same manner as petroleum oils are used in this country.

In Sweden attempts are being made to produce ethyl alcohol from sulfite liquors and the results are claimed to be quite satisfactory, but while these are steps in the right direction, the great problem affecting these industries still remains unsolved.

In this connection I do not think it amiss to point out another incongruity of laws as enforced in various countries and the discrimination shown against certain products. One of the greatest wastes in this country is that of the lumber industry. The waste in that particular industry is appalling and when we recall the strenuous efforts toward conservation of our natural resources, one stands aghast at the wanton waste still going on in that industry, for wherever you see a lumber mill of large capacity you will invariably find a burner installed where such wood waste as cannot be used in the production of steam is incinerated, and millions of dollars worth of material escapes unused into the air in the form of gases.

During the last few years an industry has been started in this country based upon the observation that cellulosic materials can be converted into reducing sugars, from which ethyl alcohol may be produced. There is only one plant in operation thus far, but the results obtained seem to indicate that this new method of producing ethyl alcohol is commercially feasible and lucrative. The cash capital invested in this plant amounts to $1,000,000. The product obtained is of the very highest grade, practically free from fusel oils and surpassing that produced in grain distilleries, yet the most natural outlet for ethyl alcohol is closed to this industry, because our laws provide that only grain-distilled spirits may be used in the compounding of whiskeys. In Canada, however, no such restrictive legislation exists because there the law simply provides that ethyl alcohol may be used irrespective of its source. It would not be surprising, therefore, if the development of this new industry would prove speedier in Canada than in this country.

Of much interest to chemists is a bill recently introduced in Congress by Representative Falson of North Carolina, providing for an appropriation of $400,000 to enable the Department of Agriculture to procure economical methods for the production of artificial fertilizers by means of electricity. It would seem that official circles have taken cognizance of the fact that the saltpetre deposits in Chile are not far from complete exhaustion, and that our lawmakers have arrived at the conclusion that they can rely upon the chemist to meet the situation—producing a cheap nitrogenous fertilizing material in place of saltpetre, which can be secured in unlimited quantities.

You all know that the utilization of nitrogen from the air by the combination of nitrogen and oxygen of the atmosphere with the formation of nitric acid is an accomplished fact.

In the form of a new chemical compound, called calcium cyanamide, which is produced by combining nitrogen from the air with calcium carbide, a plant food is obtained which, as a fertilizing agent, is as efficient as Chile saltpetre or ammonium sulphate. The production of these substances from atmospheric nitrogen will therefore remove the anxiety of many writers on economics concerning the difficulty of feeding an ever-increasing population, owing to the gradual exhaustion of the soil.

Since nitric acid is also used largely for nitrating glycerin, cotton and cellulose, and since these nitrated products are the principal constituents of the smokeless powder and high explosives used by the armies and navies of the world, it is apparent that aside from its importance from economic considerations, a process of making nitric acid independently of Chile saltpetre will become of extreme importance in case of war, for it removes the danger of being cut off from the supply of Chile saltpetre by a hostile navy.

As yet, the principal production of nitric acid from atmospheric nitrogen is centered in Norway, because that country has natural water power of a tremendous magnitude, with the further advantage of being located within easy reach of the principal markets abroad. Even in Norway, however, restrictions have been placed by law upon this new industry—the law providing in effect that only citizens of Norway may be engaged in the exploitation of these natural water powers. This caused the severance from the Norway enterprise of Dr. Schoenherr, one of the pioneers of this new industry.

The time at my disposal does not permit of enumerating all that has been accomplished in the utilization of industrial wastes through the compelling force of legislation. The aniline industry, the production of sulphate of ammonia from gas residues, of copper as from pickling liquors in steel and wire works, of copper, zinc and nickel from plating works, of fats and soaps from textile mills, and the products obtained in the reduction of garbage would all come under this heading. The last named subject alone is not only of the greatest importance and greatest interest, but in itself would suffice for a complete address.

I believe I have shown that what may at first have seemed oppressive legislation actually developed into progressive legislation, and led to the building up of important chemical industries, which, in point of commercial value, as well as in point of direct benefit to mankind, rank second to none. And now when fears are expressed regarding the commercial and industrial future of this country because of the present tendency to disband large industrial organizations and corporations, I believe the chemist has no cause for apprehension, for it is the chemist, first of all, who is sought in times of need. His services are appreciated all the more when competition calls for a greater exercise of scientific knowledge and of technical skill. This holds good even with respect to the effects of the new tariff. While the removal of a high protective tariff may bring hardships to certain industries, the ingenuity of the chemist and chemical engineer will assert itself and lead us to conditions possibly more equitable than they have been in the past. I believe that it will always be a case of history repeating itself, and I cannot see other than a most hopeful future for the chemical industries of this country.

## The Dunn Pulverized Coal Burner

BY G. A. ROUSH

One of the most important improvements in recent years in the manufacture of Portland cement is the introduction of the powdered coal burner in the kilns for the burning of the cement clinker. The wide success of pulverized fuel in this style of furnace has led to numerous attempts to apply it to various metallurgical operations, but without much success until recently. Probably the best known installation for metallurgical work is at the plant of the Canadian Copper Company, Copper Cliff, Ont., where 50 tons of pulverized coal per day are burned in the reverberatory matting furnaces. After an examination of the Copper Cliff installation it has been decided to put powdered coal burners in the reverberatory furnaces of the Anaconda Copper Company, at Anaconda, Mont.

The principle of the pulverized coal burner is, by means of a screw or some other device to feed a continuous stream of powdered coal into a blast of air issuing from a nozzle at high velocity, and then to convey this mixture of coal and air to the furnace, where the coal dust is ignited by the heat radiated to it from the walls of the furnace. The main difficulties encountered are securing a perfectly uniform feed of coal dust, and getting it evently distributed and suspended in the blast of air. These difficulties may result in incomplete combustion or an unnecessary amount of excess air, and "back-flashes." A form of burner that has practically entirely overcome these difficulties has been developed by Mr. William R. Dunn,[1] Superintendent of the Vulcanite Portland Cement Company, Vulcanite, N. J. The fact that this burner is now being installed for metallurgical work, and that it has a remarkable applicability both in large and small units, makes it of special interest.

---

[1] U. S. Patents 951,944, Apr. 12, 1910, and 1,028,997 June 11, 1912.

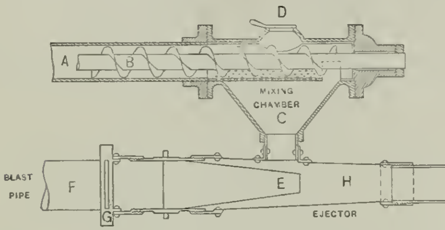

FIG. 1 PULVERIZED COAL FEEDER

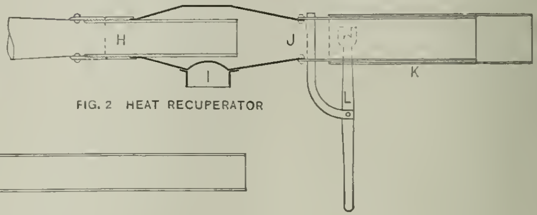

FIG. 2 HEAT RECUPERATOR

The construction of this burner is shown in Fig. 1. *A* is the feed pipe to the storage bin; *B* is the feed screw; *C* is the mixing chamber; *D* is an air valve; *E* is the air nozzle from the blast pipe *F*, the supply of air from which can be regulated by the gate valve *G;* *H* is the ejector to carry the mixed coal dust and air to the furnace. The important point in the construction of the burner is that, instead of allowing the coal to drop to the air nozzle just as it is fed by the screw, with more or less irregularity due to a slight amount of adhesion of the coal particles, the coal is carried along by the screw and gradually fed out through the perforations in the feed plate, the size of the perforations and the speed of the screw being so regulated that the coal just reaches the end of the perforated plate, for the maximum capacity of the feeder. This method of feeding completely does away with irregularities in the coal supply, and at the same time gives a more uniform suspension of the coal dust by drawing in a portion of the air through the valve *D* by the injector-action of the air jet at *E*, the air thus drawn in mixing with the coal in the chamber *C*, instead of depending, for the entire distribution of the coal dust, on the action of the air jet from *E*. This uniformity of feed and suspension makes it possible to regulate the air supply very closely, so that only a small amount of excess air will be required by the combustion, and entirely does away with the "back-flashes" that result from lack of uniform mixing of the air and coal. By regulating the valves *D* and *G*, the proportion of the total amount of air required that is mixed with the coal in *C* can be controlled, as demanded by the composition of coal, and other conditions of combustion.

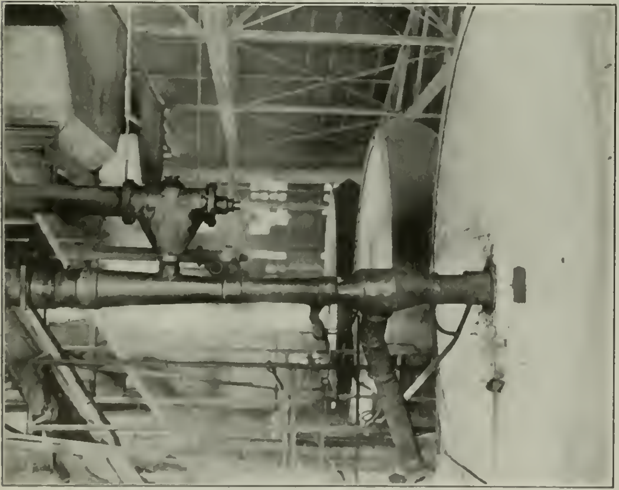

FIG. 3—POWDERED COAL BURNER (CAPACITY 2600 LBS. PER HOUR)

As applied to the cement kiln, the burner is supplied with the "heat recuperator" shown in Fig. 2. Only about two-thirds of the air required for the combustion is supplied at *D* and *G*, the remainder being drawn in through *I* by the injector-action of the blast of air issuring from the ejector *H*. From *I* a pipe leads to the pit under the kiln into which the hot clinker is discharged, so that the air drawn in is slightly preheated. This of course amounts only to a small saving, but since the cost is no more, it is worth while.

The length of the pipe leading into the kiln can be regulated by the sliding sleeve *K* and the lever *L*. The distance from the kiln wall to the end of the pipe has considerable influence on the shape of the flame.

Fig. 3 shows an installation of these burners in the Vulcanite plant, burning 2600 lb. of coal per hour, in kilns 125 ft. long, 7 ft. inside diameter and 8 ft. 6 in. outside diameter, using an air pressure of 8 oz. and a coal, 94 per cent of which passed a 100-mesh sieve. Sixty-foot kilns just beyond these were burning 800 lb. per hour. The flame was about 20 ft. long and the coal ignited at only 4-6 in. from the end of the ejector pipe of the burner. The stack gases left the kiln at 500-550 deg. C. The condition of the end wall of the kiln speaks for itself in regard to the absence of "back-flashes"; these always smut and blacken the wall, but this wall had not been whitewashed for over 30 months.

The substitution of these burners for oil burners in these kilns resulted in a saving of approximately 75 per cent of the fuel cost in calcining, and at the same time, the capacity of the kiln was increased by some 25 per cent.

These burners are working satisfactorily in units as small as 50 and 75 lb. per hour, and it is thought that these smaller sizes can be successfully applied to steam boilers, with a considerable saving of fuel.

Judging from the characteristics and construction of this burner, and from its past record it is probable that other metallurgical applications will soon be developed.

# Concentration of Complex Sulphide Ore from the Mary Murphy Mine

BY H. C. PARMELEE

The concentrating mill of the Mary Murphy Gold Mining Co. is situated near Romley, Colo., about 25 miles southwest of Buena Vista, on a branch of the Colorado & Southern Railway. The mines are located in one of the oldest districts in the state, and have been largely productive for 34 years. They were discovered in 1874, and the first extensive work was done in 1879. At various times during the history of the property, reduction plants have been built and operated—an old mill at Romley, and a smelter at Buena Vista. The present mill was built last year and has been in operation since last February.

The mines produce two classes of ore: relatively high-grade gold-silver ore, oxidized and suitable for direct smelting; and low-grade ore containing mixed sulphides of lead, zinc and iron, which must be concentrated and separated into products suitable for lead and zinc smelting.

The valuable metals in the milling ore are gold, silver, lead, zinc and copper, none of which exists in sufficient quantity to make the ore valuable for itself alone. Thus, the assay value of about 4000 tons of ore crushed in September was: gold, 0.25 oz. per ton; silver, 3.1 oz. per ton; zinc, 8.7 per cent; lead, 5.4 per cent (wet); copper, 0.6 per cent. Both mineralogically and physically the ore falls within that class denominated "complex," and the concentration problem is one of securing the best economic recovery rather than the highest metallurgical saving.

### A Complex Milling Problem

The complexity of the problem is increased by the physical occurrence of the precious metals and base minerals. The gold occurs free and usually finely disseminated, and the sulphides are generally fine-grained and intimately mixed. The preparation of the ore by crushing and grinding thus becomes the crucial feature of the process. In order to make a high gold recovery the ore should be ground comparatively fine; on the other hand, this procedure entails high loss of the lead and zinc minerals, both of which should be recovered as coarse as possible. Grinding machines that are best suited to the liberation of the gold and silver are inappropriate for the preparation of the base minerals for concentration. The whole problem thus resolves itself into finding and maintaining that happy medium between metallurgical loss and economic recovery of the several metallic constituents, which shall finally result in the greatest net profit for the whole operation.

It has been stated that the gold occurs free and finely disseminated. Metallic gold has never been observed in any of the ore deposits or specimens. Nevertheless a considerable quantity is recognizable by amalgamation; and there is a sporadic occurrence of coarse gold in the ore, for occasionally it is found on the jig screen in nuggets as large as 1/3 in. in diameter.

The methods of concentration employed at the Mary Murphy mill are shown in detail on the accompanying flow-sheet, Fig. 1. In brief, the features of the process are as follows: Coarse concentration begins on jigs, the limiting sizes of the feed being 4.75 mm (3/16 in.) and 1 mm. The portion minus 1 mm is classified for treatment on tables and vanners. The coarsest clean concentrate produced is galena from the hutch of the first compartment of the jig, the screen used being 2 mm. The coarsest tailing discharged is the finer portion of the sand from the table treating the coarsest grade of the minus 1 mm feed. Amalgamated plates and carpets are used for the recovery of free gold and silver.

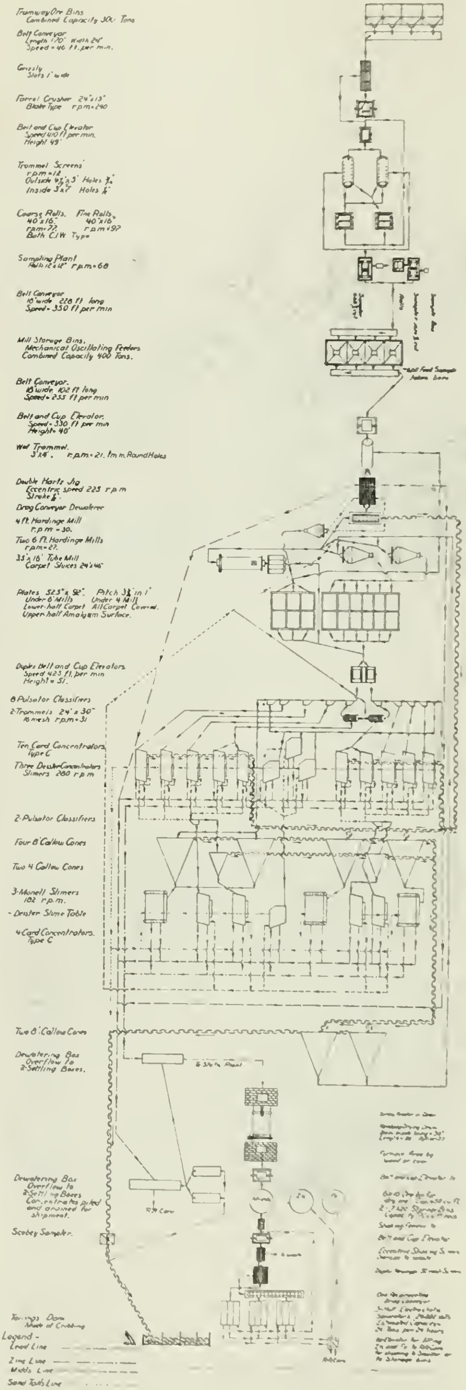

Fig 1 FLOW SHEET of the MARY MURPHY MILL

Final zinc concentrate is produced only by electrostatic separation of the zinc-iron middlings from the various tables.

### Arrangement of Plant

The mill site is located at the mouth of the Golf tunnel, a cross-cut driven before the mill was erected, and which ultimately will be connected with the mine workings and used for the transportation of ore. At present ore is delivered to the mill by aerial tramway. A general view of the mill is shown in Fig. 2, and a view from the opposite side, showing the mill terminal of the tramway, in Fig. 3.

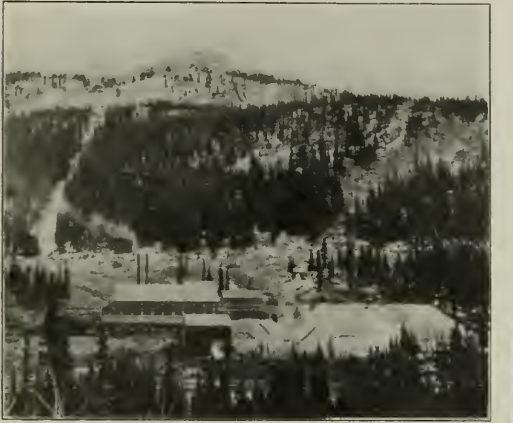

FIG. 2—CONCENTRATING MILL, MARY MURPHY G. M. CO., ROMLEY, CHAFEE CO., COLO.

The concentrating and electrostatic-separating units are separately housed, the latter being in the small building in the foreground of Fig. 2. The lowest floor of the mill is on a level with the top floor of the electrostatic plant, an arrangement which facilitates the handling of the zinc middling produced in the former and treated in the latter.

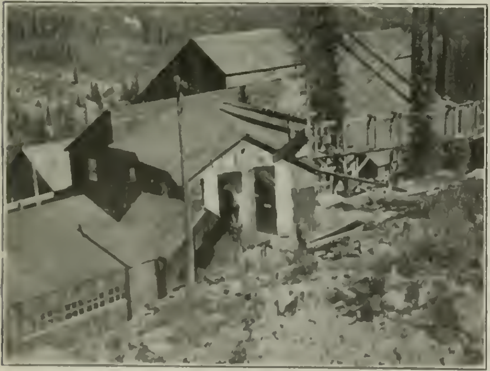

FIG. 3—VIEW FROM ABOVE MILL SHOWING TRAMWAY TERMINAL.

The concentrating machinery in the main mill is arranged on three floors. On the upper floor Card and Deister tables are placed symmetrically on each side of the central duplex wet elevators which deliver pulp to duplicate lines of Richards launder-type pulsator classifiers. A suggestion of this arrangement is given in the flow-sheet, and is shown also in Fig. 7. On the middle floor are Card and Deister tables and Monell vanners, the former retreating middlings from the corresponding tables above, and the latter thickened slime. The bottom floor is devoted to the regrinding machinery, amalgamating plates, and collection and storage of concentrates.

The arrangement of the entire plant permits of flexibility in operation. Storage bins for crude and crushed ore have ample capacity to insure steady operation of the mill without interference from the ordinary delays on the tramway or in the crushing department. The latter is designed in generous proportions, and usually prepares in 8 hours the mill feed for a 24-hour period. The arrangement of the upper and lower table floors in right and left-hand units, in combination with two pulp elevators, makes it possible on occasion to divert temporarily the entire feed to one side or the other.

The regrinding machines, one 4-ft. and two 6-ft. Hardinge mills, and one $3\frac{1}{2}$-ft. by 16-ft. tube mill, have more than sufficient capacity to meet the daily demand, so that, according to a recent change in operation, the small Hardinge can always be kept in reserve. In addition to the convenient arrangement and ample capacity of the machinery, there is plenty of room in the mill for making additions or alterations, and for the storage of concentrates during a part of the winter when railroad transportation is discontinued.

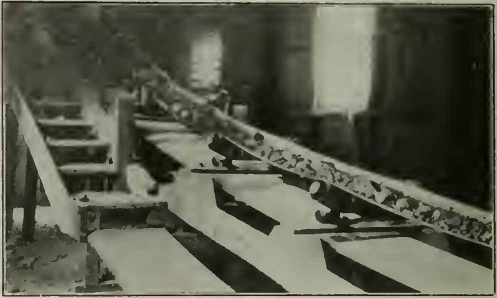

FIG. 4—SORTING BELT BETWEEN CRUDE-ORE BINS AND CRUSHER

### Crushing, Grinding and Sampling

Referring to the treatment in greater detail: The ore is conveyed from the crude-ore bins to the grizzly and crushed by means of a belt, shown in Fig. 4. From this belt the final sorting of waste is made, supplementing similar work in the stopes and at the upper tramway terminal. On an average, over one ton of waste per day is sorted out. In September the waste at this point amounted to 36 tons, or 1 per cent of the ore crushed. The main object of the sorting is the elimination of wood, pieces of steel, frozen dynamite, etc.

All of the ore is crushed and rolled to pass a 3/16 in. screen. Crushing and grinding are done dry, but provision is made to run the rolls wet in case the mine ore should become so moist as to stick badly. With wet roll crushing it would be necessary to dewater the product before delivery to the mill storage bins, and for this purpose a drag dewaterer is ready for use when occasion demands. The trommels carry two screens, inner and outer, with $\frac{5}{8}$-in. round holes, and 3/16-in. slots respectively. Their oversizes are reground in coarse and fine rolls; the undersize of the outer screen, 3/16-in. (4.75 mm.), is the finished product.

Before delivery to the mill storage bins the ore is sampled. The stream of ground ore falling vertically from the screens is cut at regular intervals by buckets supported by endless chains traveling horizontally. The first cut is reground in rolls and again sampled in a similar manner, giving finally a sample amounting to 0.1526 per cent of the ore crushed. The reject from the sampler is conveyed to the distributor above the storage bins, shown in Fig. 6.

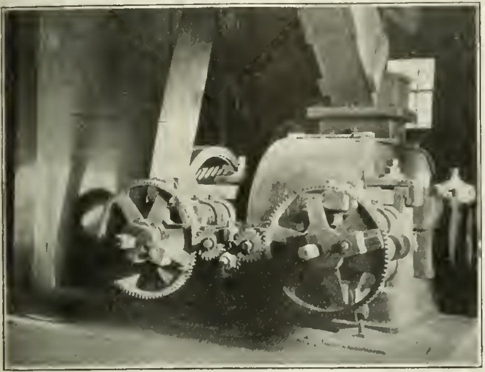

FIG. 5—ONE OF TWO 40-IN. BIG 16-IN. ROLLS, WITH DRY ELEVATOR BETWEEN

The automatic sample represents the metal contents and tonnage of ore crushed and delivered to the mill storage bins each day, but it offers no check on the ore milled during the day on which the sample was taken. The daily mill-feed is hand-sampled every 30 minutes as it leaves the storage bins to enter the concentrating system. Except for the fact that the mill-feed probably is more uniform in value than the mine ore, due to the mixing accomplished during crushing, grinding and distributing, the hand sample is likely to be less reliable than the automatic; and a closer check on the mill work might be obtained through a second automatic sample of the actual daily mill-feed. As far as gold is concerned, however, the tailing for any one day has little relation to the actual feed for that day; a feed temporarily high in gold shows higher gold loss in the tailings for a week or more.

### Jigging

Water is added to the ore at the wet trommel, where the split is made between jig and table feeds. The trommel screen has 1 mm round holes; the oversize constitutes the jig feed and the undersize flows first over carpets and thence to the duplex elevators, classifiers and primary tables.

The work of the jig necessarily varies from time to time with the nature of the feed. It is intended to produce a clean galena concentrate from the hutch of the first compartment; zinc-lead-iron middlings from the hutch and side gate of the second compartment; and tailings of quartz and rhodonite still enclosing some mineral. The production of concentrate will occur only when the ore carries comparatively coarse-grained galena; otherwise, when the sulphides are fine-grained and more intimately mixed, middlings will be produced from both compartments.

Both the midding and tailing require regrinding, but in a different degree. The flow-sheet shows the middling flowing to a 4-ft. Hardinge mill, and the tailing distributed among two 6-ft. Hardinge mills and one tube mill.

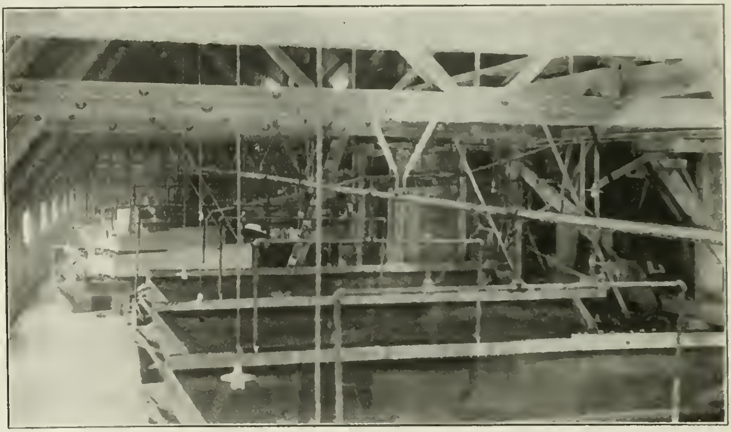

FIG. 7—UPPER TABLE FLOOR. TABLES ARRANGED AT EITHER SIDE OF DUPLEX ELEVATORS IN CENTER

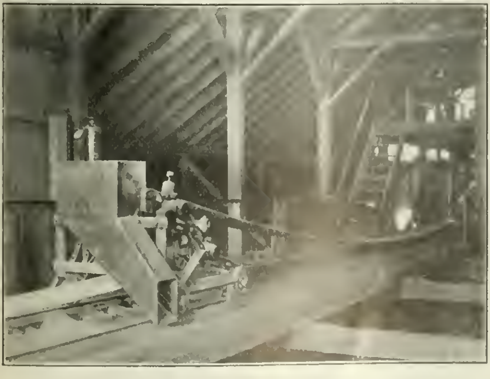

FIG. 6—DISTRIBUTOR ABOVE CRUSHED-ORE BINS

### Effect of Regrinding Mills

Experience with the Hardinge mills on this ore indicates that they are satisfactory in regrinding tailings of quartz and rhodonite, but are not so well suited to the regrinding of middlings, as they produce too much mineral slime. For this reason one of the important changes recently made in the treatment is the substitution of a set of 14 in. by 27 in. rolls for the 4-ft. Hardinge mill. These rolls are to be set close, and are expected to accomplish the regrinding of the middling with the production of less slime.

The following figures are fairly typical of the work done in the four regrinding machines. The pulp samples were taken on the same day, with the plant running under normal conditions, treating 125 tons of ore in 24 hours. The screen tests were made on dry pulp. Assays are given in ounces gold and silver per ton, and per cent of lead and zinc. The desired grade in the discharge lies between — 60 + 200.

| — 200 | 51.22 | 0.68 | 6.8 | 8.8 | 24.3 |

A noticeable feature of the analyses, particularly in the discharged pulps, is the higher grade of lead and zinc in the fine sizes, and of gold in the coarse. This suggests the possibility of undue loss in the extreme sizes: gold in coarse tailings, and base minerals in slime.

### Recovery of Free Gold and Silver

From the flow-sheet it will be seen that the pulp is run over amalgamated plates or carpets, or both, prior to table concentration. The carpet washings are dressed on a table, and the rich concentrate amalgamated in a grinding pan. Another product treated by pan amalgamation is the lead concentrate from the first four riffles of the primary Card tables treating the coarsest pulp. This part of the lead concentrate is very high grade in gold. If mixed with the product shipped to the smelter, it would tend to make sampling more difficult and settlements less satisfactory. Probably it is better to recover this gold as bullion than to run the risks attendant on sampling a "spotty" concentrate.

The following figures show the assay value in ounces per ton of the carpet washings on three consecutive days, and of the concentrate from the first four riffles of the coarse Card tables.

| | Gold | Silver |
|---|---|---|
| Carpet Washings (a)................ | 10.86 | 13.5 |
| Carpet Washings (b)................ | 18.50 | 18.5 |
| Carpet Washings (c)................ | 15.88 | 18.1 |
| Rich Card Conc...................... | 40.05 | 38.3 |

Both Wilton and Brussels carpets have been used for gold recovery, and tests have been made to establish their comparative value as gold-saving devices. Below are given the weights and assay values per ton of carpet concentrates recovered on the two kinds of carpet, under the same conditions of feed for a period of 4 hours. The superiority of Brussels is apparent.

| | Weight recovered | Gold Oz. | Silver per ton | Lead per cent. | Zinc per cent. |
|---|---|---|---|---|---|
| Wilton ........ | 16 oz. | 36.2 | 35.6 | 35.7 | 11.2 |
| Brussels ..... | 35 oz. | 83.8 | 47.2 | 48.4 | 10.5 |

### Table Concentration

Card tables were selected for use in this instance as being better adapted to the treatment of an ore containing several minerals to be separated. Deister slime tables and Monell slime vanners are used on the finest sand and slime pulps respectively. Richards pulsator classifiers of the launder type are used to classify the pulp fed to the tables on the upper floor. The flow-sheet shows similar classifiers ahead of the tables retreating middlings on the second floor; but these are not in use at present, as assays of the tailings from these tables, with and without classified feed, showed no appreciable variation. A further advantage is gained by keeping out of the system the additional water required by these classifiers.

The flow of pulp and disposition of products in this part of the mill can be comprehended better by reference to the flow-sheet than from written description.

Many tests have been made in this department, in an effort to see in what direction improvement could be made. All results seemed to point toward the possibility of an increase in mill capacity without material increase in tailing loss. This has practically been accomplished, and the plant is now treating 150 tons per day instead of the 100 for which it was designed. On one occasion, when one of the duplex wet elevators was being repaired, half of the Card and Monell tables were shut down and the entire feed diverted to the other half, thus doubling the load. This condition prevailed for 12 hours, and the tailing discharged from the mill was not appreciably different from that for the balance of the 24 hours with all tables in use. The assays are given below:

| | Gold Oz. | Silver per ton | Lead per cent. | Zinc per cent. |
|---|---|---|---|---|
| Tailing with all tables running | 0.04 | 1.5 | 1.2 | 3.8 |
| Tailings with half of tables running under double load.. | 0.03 | 1.2 | 1.5 | 4.3 |

### Losses in Various Tailings

The following tabulation of assays on tailings from the tables on the upper floor illustrates a condition already referred to, *viz.*, that the losses of precious and base metals tend to decrease and increase, respectively, the finer the ore is ground:

| Table | Classifier spigot | Gold Oz. | Silver per ton | Lead per cent. | Zinc per cent |
|---|---|---|---|---|---|
| 2 Cards ............ | 1 | 0.15 | 1.4 | 0.7 | 2.8 |
| 1 Card ............... | 2 | 0.11 | 1.0 | 0.5 | 2.1 |
| 1 Card ............... | 3 | 0.04 | 0.7 | 0.4 | 2.2 |
| 3 Deister ........... | 4 | 0.04 | 0.7 | 0.7 | 2.3 |
| 1 Card ............... | Overflow | 0.03 | 1.0 | 0.7 | 3.8 |

This condition is confirmed by many screen tests and assays on the unfinished products from various points in the concentrating system, as well as in the final mill tailing. It complicates the problem of recovery and taxes our known methods of physical concentration almost to the limit. In fact, it is such conditions as exist in this instance that urge some of our metallurgists to seek and hope for successful chemical methods of treatment. The following tabulation on the general mill tailing is added to further show the condition referred to. Assays of gold and silver are in ounces per ton, and lead and zinc in per cent.

| Mesh | % | Gold | Silver | Lead | Zinc |
|---|---|---|---|---|---|
| Original sample | | 0.07 | 2.1 | 2.4 | 4.5 |
| + 35 | 4.99 | 0.15 | 2.4 | 2.1 | 4.6 |
| + 65 | 19.11 | 0.16 | 1.5 | 1.0 | 3.1 |
| + 100 | 10.25 | 0.22 | 1.4 | 0.7 | 1.7 |
| + 200 | 24.93 | 0.09 | 1.5 | 0.8 | 1.7 |
| — 200 | 40.72 | 0.07 | 3.2 | 2.9 | 7.3 |

### Slime Concentration

The commercial value of high-grade products is well shown in the slime concentrates. The flow-sheet indicates that the concentrates from the Monell vanners are split into two products: one which is mainly galena, of sufficiently high grade to be mixed with the regular lead concentrates, and the other a mixture of pyrite, blende and silica. The latter is not a profitable commercial product, as it contains only about 30 per cent zinc and 9 per cent lead. Tests show that this material can be retreated on a Wilfley table, and separated into lead-iron and zinc concentrates which will be more valuable than the original feed. When this plan is put into effect, the Monell table will be operated so as to deliver a more silicious zinc slime, and this will be separated on the Wilfley into (a) lead concentrate, (b) zinc concentrate and (c) tailing which will be returned to the mill system. The Wilfley will be equipped with a wheel for the continuous return of its own middling.

It is by attention to such details as the foregoing that economic success is won in the concentration of complex ores. Products of high commercial value must be sought rather than those which represent primarily the greatest saving. Smelting schedules on base metals, particularly zinc, are so arranged that a difference of only a few per cent in the grade of concentrates will determine the profit or loss on the operation. The Monell zinc slime just considered brings a ridiculously low price in the market, merely because it falls below the grade desired by the smelter. Its commercial value can be considerably increased by redressing it, and the net economic recovery may be increased even though a metallurgical loss be sustained in the operation. Re-treatment of products may complicate the flow-sheet, but is justified as long as more profit can be made.

### General Mill Results

The finished products from the concentrating mill are: bullion, lead concentrates from jigs and tables, zinc-iron middlings, and Monell zinc slime. The zinc-iron middlings are treated in the electrostatic plant. Gold and silver occur in all of the mill products, as shown in the following tabulation of results for September. Lead assays are made wet:

| | Weight, tons | Gold, oz. | Silver per ton | Lead, per cent. | Zinc, per cent. | Copper, per cent. |
|---|---|---|---|---|---|---|
| Ore crushed .......... | 3989 | 0.25 | 3.1 | 5.4 | 8.7 | 0.6 |
| Lead concentrate ..... | 138 | 2.26 | 12.4 | 48.8 | 10.8 | 0.7 |
| Zinc-iron middling..... | 273 | 0.32 | 7.0 | 7.2 | 38.1 | 2.3 |
| Zinc slime ............ | 34 | 0.19 | 7.1 | 9.6 | 30.9 | 1.5 |
| Tailing ............... | ... | 0.07 | 1.7 | 1.4 | 4.0 | 0.3 |
| Amalgam: From pan, 220.6 oz.; from plates, 99.1 oz. | | | | | | |
| Saving calculated from heads and tailings ............ | | 75.9% | 50.6% | 86.7% | 58.6% | 55.0% |

### Tailings Impounded

The mill tailings are impounded in a series of terraced ponds, both because it is an unwise policy in this day to put tailings beyond possible recovery, and because it is necessary to keep them out of the streams. As far as can be seen at present the tailings have no value, but if metallurgical methods should become sufficiently improved to treat such material profitably, it will be available without great expense. Possibly when that time arrives the successful method can be applied to the crude ore with better success than now attends concentration.

### Electrostatic Separation

The Huff electrostatic system[1] is used for the separation of the zinc-iron middling into merchantable products for zinc and lead smelting. The equipment and general arrangement of the plant are shown on the flow-sheet. The capacity is approximately one ton per hour, except on a slime feed, when it falls about one-half. The ore is first dried in a wood-fired rotary kiln, consuming one cord of wood per day. The drier is lined with fire-brick. Some difficulty has been experienced in keeping the lining intact, but recently this trouble has been overcome by setting the brick in a mortar of cement and asbestos.

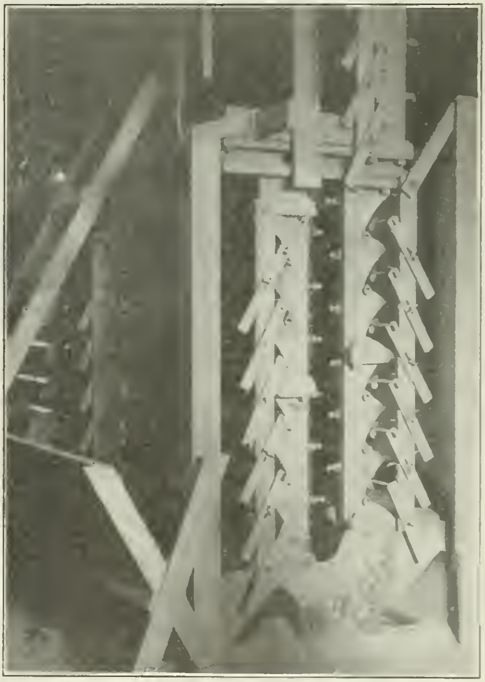

FIG. 8.—PORTION OF ELECTROSTATIC SEPARATORS

The dried pulp is separated into coarse and fine grades by a Newaygo 50-mesh screen, and the plus and minus sizes are delivered to the three Huff separators. These are of the "toboggan" type, shown in part in Fig. 8. The upper set of electrodes give a rough separation of iron from zinc, and each of these products is finished on one of the two lower sets.

A middling product results from the final separation, which requires further treatment. Several methods of handling this material have been experimented with: it has been added continuously to the original feed, and it has been accumulated and treated separately. The latter method results in a further complication: a second middling is produced which, for a curious and unexplained reason, refuses to yield a further separation either by electrostatic treatment or wet dressing. The result is a final accumulation of a comparatively worthless product.

---

[1] Descriptions of this process have appeared in this journal, May 1910, p. 295, Nov., 1910, p. 636, Jan., 1912, p. 49, Oct., 1913, p. 581.

The opinion generally maintained on the retreatment of electrostatic middling is that it should be added continuously to original feed, and this method may be finally adopted at this plant.

The flow-sheet shows electrostatic treatment of the zinc slime from the Monell vanners. The greatly reduced capacity of the electrostatic separators on this fine material, combined with the unsatisfactory results obtained in regard to grade of product, has led to the discontinuance of this practice.

FIG. 9.—SLIME SETTLING PONDS

As stated before, an effort will be made to beneficiate the Monell slime by a retreatment on a Wilfley table.

The following results are typical of the electrostatic work done on different feeds:

*Table Middlings.*

| | Gold | Silver | Lead | Zinc | Copper | Iron |
|---|---|---|---|---|---|---|
| Feed ... .... | 0.40 | 6.8 | 7.2 | 35.9 | 2.6 | 10.8 |
| Zinc product.. | 0.40 | 5.2 | 5.6 | 47.2 | 0.9 | 5.2 |
| Iron product | 0.41 | 8.6 | 9.8 | 15.2 | 5.1 | 24.2 |
| | | | | | | |
| Feed ..... ... | 0.42 | 6.1 | 7.6 | 37.8 | 1.3 | 10.7 |
| Zinc product... | 0.24 | 5.1 | 5.0 | 51.8 | 0.6 | 3.8 |
| Iron product.. | 0.52 | 9.1 | 10.3 | 17.8 | 2.5 | 23.0 |

*Retreatment of Electrostatic Middlings.*

| | Gold | Silver | Lead | Zinc | Copper | Iron |
|---|---|---|---|---|---|---|
| Feed | 0.52 | 9.1 | 10.2 | 28.2 | 1.4 | 14.0 |
| Zinc product | 0.56 | 9.8 | 11.1 | 34.8 | 0.7 | 9.4 |
| Iron product | 0.62 | 9.9 | 9.0 | 12.8 | 5.0 | 26.8 |

*Monell Zinc Slime.*

| | Gold | Silver | Lead | Zinc | Copper | Iron |
|---|---|---|---|---|---|---|
| Feed | 0.22 | 6.8 | 8.8 | 31.0 | 1.6 | 10.0 |
| Zinc product | 0.34 | 6.1 | 11.9 | 34.2 | 1.6 | 8.5 |
| Iron product | 0.52 | 10.0 | 8.7 | 16.1 | 5.0 | 22.1 |

The dust formed in the process of drying the middlings appears to be inconsiderable, amounting to only two tons in four months. Ninety-two per cent of it is finer than 200-mesh.

It assays 0.32 oz. gold and 9.9 oz. silver per ton, 8.0 per cent lead, 24.5 per cent zinc, 3.9 per cent copper and 8.5 per cent iron.

It is practically without commercial value, and would be a difficult material to treat by wet or dry methods of concentration.

In conclusion the writer wishes to express his appreciation of the courtesy of Mr. George E. Collins, general manager, and members of his staff, for the facilities offered in collecting these notes.

# Chemistry of Salt Water Cement

## Notes on Sand, Stone and Gravel

BY HARRISON S. TAFT

1. The success to be attained by placing concrete structures in sea water depends upon, first, the possibility of using cement in salt water, and, second, an economical design. Without doubt a great many prominent engineers hesitate to recommend the placing of concrete structures in sea water more from a chemical point of view perhaps than from a structural one. If the material out of which the structure is to be built cannot be depended upon to maintain its integrity when exposed to the elements, the very best design will not solve the problem.

Therefore the chemistry and manufacturing side of the cement industry becomes a question of prime and vital importance as regards cement to be used in sea water structures. The next question is that of impermeability; otherwise the concrete might slowly deteriorate under the action of the chemicals in sea water, since perhaps it is impossible to reduce such actions to a negative quantity. In freezing climates this question of impermeability becomes a very serious one, due to the destructive action of alternate freezing and thawing.

2. **Cement.**—The first and chief difficulty that has to be overcome in using concrete in sea water is "the peculiar chemical disintegrating action of the magnesium and other sulphate contents of ocean water upon the alumina compounds in the cement," followed "by the abrasive action of the water of the ever-restless sea" upon the chemically affected and softened concrete.

To overcome the chemical action of the sea water upon concrete the Germans have placed upon the market a brand of cement called "iron ore cement," wherein the alumina content of a cement is partly replaced for fluxing purposes by iron which is not affected deleteriously by the magnesium and other sulphates of the salt water; thus inoculating the concrete, as it were, against attack. The world-famed Teil Cement Works does not allow more than 2 per cent alumina and absolutely no free lime in the cement which they manufacture for use in concrete structures standing in sea water.

Another German product called Puzzolan-Portland Cement, especially devised for use in sea water, has been on the market some 16 to 18 years. This product is a mixture of Portland cement and a natural puzzolan (a volcanic ash), or of a Portland cement and an artificial puzzolan (blast furnace slag of a certain chemical composition), the mixture being 30 to 60 per cent puzzolan and 50 to 70 per cent Portland cement.

The chemical action in hardening results in a Puzzolan-Portland hydraulic cement invulnerable to sea water. Although the mixing can be done on the job, it is far preferable to pulverize the two ingredients together in the mill at the cement factory.

A set of extensive tests made by the German government shows higher strength for Puzzolan-Portland cement concrete both in tension and compression than for pure Portland cement concrete. It has also been demonstrated that the former resists salt water far better than the latter. From an economic point of view in producing resistance to the action of sea water a barrel of Puzzolan-Portland cement has been found to be equal to two barrels of pure Portland cement.

From information obtained in regard to these two German cement products, concrete made of them and placed in salt water has been giving the best and most satisfactory results. Thus a vast amount of salt water concrete construction is being carried on in Germany and other foreign countries, due no doubt to their overcoming the action between salt water and the cement.

Though there have been a number of disastrous disintegrations in using American Portland cements in salt water, on the whole American Portland cement seems to have worked quite satisfactorily in sea water.

Such cement "has the power of armoring itself against the action of the magnesium sulphates of the sea water by the formation on its exposed surfaces of a film of lime carbonate." This film appears to serve as an effective protection to the concrete structure in comparatively still waters, but where the waters are greatly agitated this film has no opportunity to form. Hence "the calcium hydrate set free by the decomposition incident to the hardening of the Portland cement is washed away," leaving the concrete stucture unprotected against "further inroads of the deleterious chemicals contained in the sea water."

To reduce the question of the chemistry of sea water cement to a more technical form:[1] "The magnesium sulphate present in sea water acts upon the calcium hydrate of the cement, forming calcium sulphate, and further, this calcium sulphate combines with the alumina of the cement, forming calcium sulpho-aluminate, which last compound gives rise to the swelling and cracking of the concrete."

Mr. O'Hara also states that though it may seem that a cement in which the alumina has been replaced by iron is desirable, it would be impracticable, however, to replace *all* the alumina in a cement by iron oxide, as "a product resulting from the burning of ferric oxide and calcium carbonate does not possess hydraulic properties." He further says that whereas it seems to be universally accepted by engineers and others that a dense concrete is impermeable to sea water, the results of tests made by him do not seem to bear out this theory, unless the cement used has the inherent qualities to resist the disintegrating action of the sea water.

In discussing the subject of mass concrete in block form for breakwater purposes, William Matthews, a prominent English engineer, says:

"In a tideway, where mass concrete is used, it is of the utmost importance that the relative sizes and proportions of the aggregate should be such as to produce an absolutely water-tight material. The infiltration of sea water into green or unset concrete and its subsequent exudation due to tidal action causes the magnesium salts in the sea water to withdraw a portion of the lime of the cement in the form of calcium salts, leaving a deposit of magnesia in its place. It is this magnesia, derived from sea water, either alone or mixed with lime from the cement, which constitutes the white substance deposited in the interstices of porous concrete between high and low water. Concrete so affected possesses but little strength and its failure is only a question of time."

As the result of his research upon the use of cement for sea water purposes, the eminent Dutch chemist, V. I. P. de Blocq van Kuffeler, Hoorn, states[2] "that the decomposition of the concrete is caused by the salts contained in sea water; the sulphates are the most to be feared owing to their action on the unstable compounds of lime which are formed during the very long period taken by the cement for hardening. Evidently it is during the first part of this period that the action of sea water is the most detrimental, i.e. when the compounds are least stable. Actual experience has confirmed this theory."

He also says that "when such material as trass or puzzolanes are added to the cement, one part of the lime forms compounds with silicates, the other compounds mentioned becoming more stable and the influence of sea water is less to be feared"; that "fine trass increases the impermeability of the mortar"; and "if the concrete has been hardened in a damp atmosphere the influence of the trass is still more marked."

Irrespective of the brand, a cement to be successfully used in salt water must be of the very best quality, of a fine pulverization, and thoroughly analyzed and tested for its chemical properties. Every means should be taken to avoid too much alumina in a cement that is to be used in salt water. The per cent of alumina should be low, that of silica high. The cement should also be as free as possible from gypsum.

A cement of the slow hardening order should be avoided. Distinction between "setting" and "hardening" of cement should be kept in mind. A slow setting but quick hardening cement is the proper kind to use in salt water.

Not only must the cement manufacturers provide the engineer and the contractor with a cement of the proper chemical constituents, but the concrete made from said cement must be dense in order to fulfill all the requirements of a salt water concrete. This apparently is what the Germans have been doing, and it explains why they are able to get such excellent results in concrete work in Germany as well as in other foreign countries. It is an exceedingly important question for domestic cement manufacturers to consider.

As considerable stress has been laid above on the German method of manufacturing cement for sea water purposes, it is fitting to still further consider what Herr Blocq van Kuffeler says upon the question of using cement in concrete placed in salt water. He states that the following points should be most strictly adhered to in using concrete in salt water:

(a) Artificial (slow-setting Portland) cement of first-class quality and hardening very uniformly, should be used to the exclusion of all others.

(b) The mixing of the material and the ramming of the concrete in strong and tight casings must be performed with the greatest possible care.

(c) The use of trass (or puzzolanes) is recommended.

(d) The concrete must be compact and the composition of the mortar should not be below 1 part cement, ½ trass and 3 sand, or I part cement, 1½ sand.

(e) Allowing the concrete to set in a damp atmosphere before placing "in situ" greatly increases its resistance to attack by sea water and is recommended where possible. When the concrete is exposed to the infiltrations of sea water immediately after manufacturing its composition should be richer.

In conclusion he says a carefully considered composition, most careful manufacture, the use of excellent cement with trass (or puzzolan) and hardening in a damp atmosphere are the most efficient means of satisfactorily ensuring the preservation of reinforced concrete in maritime works.

**3. Laboratory or Similar Tests.**—For several years past the United States Government has been carrying on a set of tests at Atlantic City and elsewhere to determine the exact fact as regards the use of cement in sea water. A preliminary report of these tests has recently been issued by the Government. Although three years is a comparatively short time for determining the absolute facts under actual conditions, the results of these tests so far published seem to indicate that the success of using concrete in sea water depends in a large degree upon careful and proper working of the material rather than upon the special brand of the cement itself. It is true that some cement works better than others in sea water, those with a low percentage of alumina giving the most satisfactory results, but with an impermeable structure as the prime factor in all cases.

Although these Government tests will no doubt in time give the concrete engineer the absolute facts as regards the situation, the engineers of this country already have the actual experience of some 18 years of foreign practice by which to guide themselves. No doubt the final results of these United States Government tests will simply substantiate what has already been learned regarding the use of cement in sea water by foreign chemists, viz.: an *impermeable mass* with a low per cent of alumina in the cement used.

---

[1] From Report of J. M. O'Hara, Southern Pacific Railway.

[2] From a paper read before International Association for Testing Materials, New York, September, 1912

In the early part of 1909 twenty-four test pieces were made of concrete and hung from one of the wharves at the Charlestown Navy Yard, Boston Harbor. These test pieces were 16 feet long, 16 inches square and made with a core for part of their length so as to provide a means of determing their permeability. Several different kinds of cement were used in making these pieces and the concrete mixed in various proportions; some of the pieces being made dense, others porous. These pieces were hung from the pier in such a way as to have their lower ends always in water, while the tops were seldom submerged. At the end of the first two years of immersion one of these test pieces showed marked signs of deterioration, while others were in good condition. Later reports go to substantiate the truism mentioned above, since the pieces made of a porous nature have deteriorated somewhat while those of a dense nature are in the same perfect condition as the day they were made.

Though these laboratory tests will go a long way in revealing the true facts and actual conditions it is necessary to guard against in the use of cement in sea water, "it must ever be kept in mind that the phenomena, both physical and chemical, in the sea cannot be reproduced exactly in laboratories on land." Consequently laboratory tests will never give the real truths of using cement, and hence concrete, in sea water as will actual experience. Thus the actual experience of foreign engineers in the use of concrete in sea water structures and the modes pursued by them are far more valuable to the American engineer than any short time test made in this country.

Admitting that laboratory tests are absolutely necessary and that the world cannot get along without them, such tests must be considered hand in hand with actual experience and as supplementary thereto. The fact that local conditions and local material will seriously alter cases brings home to the engineer the truth that he must not judge foreign experience by home conditions, and vice versa, until the actual conditions covering each are known and is used as the complement of the other.

**4. Waterproofing Compounds.**—In view of the claims made by waterproofing experts as respects the excellency of their product, it is proper to quote from an article entitled "Test of Water-Proofing Material," U. S. Bureau of Standards, No. 3, August 22, 1911: "Portland cement mortar and concrete can be made practically water-tight or impermeable (as defined below) to any hydrostatic head up to 40 feet, without the use of any so-called 'integral' water-proofing material; but in order to obtain such impermeable mortar or concrete, considerable care should be exercised in selecting good material and aggregate, and proportioning them in such a manner as to obtain a dense mixture. The consistency of the mixture should be wet enough so that it can be puddled, the particles flowing into position without tamping. The mixture should be well spaded against the forms when placed so as to avoid a formation of pockets on the surface."

"The addition of so-called 'integral' waterproofing compounds will not compensate for lean mixtures, nor for poor material, nor for poor workmanship in the fabrication of the concrete. Since in practice the inert integral compounds (acting simply as void filling material[1] OR IN THE NATURE OF A LUBRICATING MATERIAL) are added in such small quantities, they have little or no effect on the permeability of the concrete. If the same care is taken to make the concrete impermeable, without the addition of waterproofing material, as is ordinarily taken when waterproofing materials are added, an impermeable concrete can be obtained."

In connection with this part of the subject it may not be out of place to speak of "oiled concrete" for waterproofing certain classes of concrete structures. It is of such recent development that sufficient opportunity has not been given to determine its real merits for universal waterproofing purposes especially as regard concrete structures standing in sea water. So far as known there are no records "of any such tests ever having been made" and some chemists have positively stated that it will be impossible to make oiled concrete a success for sea water purposes.

On the other hand, I. Hiroi, a civil engineer of Japan, has stated: "Of more than 12,000 concrete blocks of all sizes and of different compositions, used by the writer in harbor works during the past ten years, there has not been the slightest indication of failure. On the contrary, the protection given by coatings of animal, vegetable and mineral origin to the surfaces of the blocks has rendered them almost impregnable against the incessant action of the sea. The protection thus afforded by nature, which would render a comparatively weak artificial stone, when properly made, as lasting as the natural stone used as its ingredient, is unknown in laboratory experiments."

**5. Sand, Gravel, Stone.**—The sand used in concrete placed in sea water must be clean, sharp and free from all foreign material. The stone must also be clean and sound. Gravel, if used, must likewise be clean and of proper size. The chemical composition and mineral structure of the stone, sand and gravel for use in proposed sea water concrete structures, should be known absolutely beyond all doubt. Since it is of great importance that concrete used in sea water should have the maximum density, the mechanical composition of sand and gravel should be known and modified, if necessary, by adding screened material.

For the same reason that an igneous rock or material is far better in the construction of a fireproof concrete structure, it is absolutely necessary in salt water concrete to use aggregates that will not disintegrate or fail when exposed to the elements of the salt water and the action of the sea.

The eminent expert, Mr. John R. Freeman, has called the attention of engineers to the fact that "here and there are banks of sand and gravel which, upon ordinary inspection, appear ideally perfect for making mortar and concrete, but which are nevertheless dangerous in the extreme, and all because of some ultramicroscopic content, probably similar to tannic acid (in a colloidal film around the sand grain), which works in some mysterious way to prevent the union between the cement and the sand grains."

Mr. Freeman cites an occasion where he found the site of a proposed structure what promised to be a most economical resource in a shape of excellent sand and gravel; but upon being tested some of the samples of 1:3 mix, six days in water, hardly maintained their integrity while being placed in the clamps and before any load was applied. The cement was of a brand that had given excelleat results with other aggregates.

E. E. Free, an investigator, engaged upon physical and chemical investigations for the Bureau of Soils, has noticed analogous phenomena in studying the relative fertility of different soils. Mr. Free states that:

---

[1] The portion in capital letters inserted by writer

"In popular terms the situation can perhaps best be explained by considering that an extremely thin film of a complex form of tannic acid surrounds each grain of the troublesome sand and prevents its attachment to the cement. These complex organic acids have a strong tendency to spread themselves thinly and strongly adherent over the outside of the siliceous material. The reason why one particular brand of cement is able to break through this filmy barrier so as to get a firm grip upon the sand grain is because of its containing a small quantity of some form of alkali that unites with this acid film or somehow changes its colloidal state."

It is admitted that these defective sands are the exception rather than the rule. Though some engineers and contractors may think the whole investigation a highly interesting laboratory amusement, of no value whatsoever to practical construction, the fact remains that there are sands whose availability for concrete aggregate cannot be predicted under any of the ordinary methods now in vogue, and that every so often one of these sands gets into a structure to its detriment and perhaps failure if the structure stands in sea water. Therefore the sand and stone should be tested as carefully as the cement for salt water purposes.

Of equal importance is the utmost care that must be taken in mixing and placing the concrete, in order to obtain an impermeable mass throughout. Superintendents and concrete foremen should also be careful to see that injurious acids do not get into the sand, gravel and stone of concrete to be placed in sea water by the working force urinating upon the material.[4] Great care should likewise be taken to exclude from all material entering into the manufacture of concrete such things as scraps from lunches, tobacco and the spittle of those chewing tobacco. It is known that an amount of sugar, even as small as ¼ per cent will entirely prevent a batch of cement from hardening. Since the extract from chewing tobacco contains sugar or glucose, any such extract that enters into the concrete will prevent the cement from setting. There are other organic compounds whose presence in the concrete will have a marked effect on the hardening of the cement, and the utmost means should be taken to exclude such detrimental material from all concrete to be placed in sea water.

6. **Mixture.**—In connection with the concrete dock work of the Thames River the practice seems to have been to use "a gravel of moderate size combined with two-thirds of its bulk of sand mixed with one part of cement to every two parts of sand," viz., a 1-2-3 mixture. It is stated that with such a mixture there will be no fear of the results if the concrete is *properly mixed and handled.* The concrete is also given a grout coating after it has set and hardened.

In building concrete breakwaters in Holland it has been found that mass concrete blocks made of 1 part Portland cement, ½ part trass (the trass being a Puzzoland which is found near Andernach on the Rhine), 3 parts sand and 5 parts Rhine gravel, enabled the blocks to resist the corroding action of the sea water. Of more recent date they have been using a cement-trass-concrete of 1 part cement, 1-3 part trass, 2 parts sand and 3 2-3 parts gravel.

In Germany a mixture of 1 part cement, ½ part trass, 3 parts sand, 4 parts gravel, is very often used.

During recent years a very rich mixture, viz., 1-1½-3, has been used in nearly all the important sea water concrete structures built in England and France.

In the harbor development of Otaru, Japan, a proportion of 1 part cement to 2 parts sand for the mortar gave superior results; the average concrete mixture used being "1 cement, 2 sand, 2 gravel and 2 broken stone, before the tuff was put in; the ratio equivalent by weight of the cement to the tuff being, 1 cement to ½ tuff." By volume this combination reduces to:

1.0 cement; 0.8 tuff; 3.2 sand; 6.4 ballast.

In the Netherlands Portland cement concrete with the addition of trass has been used almost exclusively. Though Herr Blocq van Kuffeler recommends a mortar of 1 part cement, ½ part trass and 3 parts sand mixture for sea water structures, he states that concrete of the above composition will remain in a perfect state of preservation "provided it has been hardened in a damp atmosphere before placing *in situ*, but is apt to give disappointment if the concrete is exposed to the infiltration of the sea water immediately following manufacture." Under the latter conditions he recommends a richer composition—at least 1 part cement, ½ part trass, 2½ parts sand. When no trass is used he says a mixture of 1 part cement, 1½ parts sand should be used. He also says that whereas mortars of 1 cement, 1½ sand and of 1 cement, 1½ trass, 3 sand can be used with safety in marine concrete work, the latter will create a saving in cost of considerable extent. It is also of great importance that the cement and the trass should be thoroughly mixed before the sand is added.

As respects the use of salt water in the manufacture of concrete, the same eminent chemist states that since the amount of salts introduced into the concrete by diffusion when the concrete is exposed to sea water is vastly in excess of any salts that might be introduced into the concrete "by the small quantity of water used in its manufacture—the use of salt water in the making of concrete is in all probability prejudicial to only a slight extent."

As in ordinary reinforcement work, when the reinforcement is complicated, a smaller size gravel should be used with their homogeneity increased, a size of not over .116 cubic inch being recommended by a leading authority for marine reinforced concrete.

Mr. I. W. Sandeman, in his paper upon "Action of Salt Water Upon Concrete," states that for salt water purposes the maximum proportion of the sand in the mortar must not be more than twice that of the cement, and the mortar must exceed the voids in the aggregate. The exact grade of the sand mixed with the cement plays an important part in obtaining impermeable concrete, a hard, coarse sand giving the best results. It was the knowledge of this important point and a thorough investigation of it that enabled the noted Italian engineer, Com. Luigi Luiggi, to construct a dry dock at Bahia Blanca, in 1902, that resulted in a perfectly water-tight job. The utmost care was taken in the construction of this dock, with special attention to the bonding of old concrete to the new.

As respects the advantages of using crushed stone over gravel, Mr. Staniford, chief engineer of the New York Dock and Ferry Department, states that his department does not find gravel a suitable material to use in mass concrete when subject to the action of sea water, and that the broken, hard trap rock, so commonly used in New York City and vicinity, gives far better results in such kinds of concrete than are obtained with gravel. From the author's own experience with broken stone and gravel, he prefers stone, especially if it is trap rock.

7. **Conclusion.**—In the final analysis, the successful use of cement in concrete structures standing in sea water boils down to the use of an impermeable concrete made of a cement low in alumina and otherwise suit-

---

[4] Notes from a paper to be published by Chas. A. Newhall. By permission.

able for salt water purposes. The former is the problem of the concrete and construction engineer; the latter the problem of the chemist and cement manufacturer. To obtain an impermeable concrete a very rich mixture must be used, the exact proportion between the finer and coarser material being dependent upon the per cent of voids.

If possible the concrete should be hardened in a damp atmosphere in order to assist the chemical reaction of setting before being placed *in situ*, or before being subject to the action of the sea water, especially so if the sections are small.

The mixing and placing should be closely watched and done with the greatest care, far more so than in the ordinary building work, in order to ensure that each particle of the sand and coarser material is well covered with cement and mortar respectively. A concrete of a medium or plastic consistency will ensure far better results than a wet or dry mixture.

"In the Netherlands experience has furnished conclusive examples as a guide for future construction, with a sufficient degree of safety, as to justify the further application of reinforced concrete in marine structures, which after all are only the work of mortals and not destined to last for eternity."

*Seattle, Washington.*

## Color Photography Applied to the Demonstration of the Microstructure of Ores

Mr. Gilbert Rigg, research engineer of the New Jersey Zinc Company, presented at the meeting of the New York section of the American Electrochemical Society, on October 17, 1913, a brief but exceedingly interesting lecture on the application of color photography to the elucidation of ore structure.

As mentioned in our report of this meeting in our November, 1913, issue (page 622), Mr. Rigg has been the first to apply color photography for this purpose. At that meeting he exhibited a striking series of Lumiere plates showing photomicrographs of ores, with resolution of the minerals present. While for mechanical reasons it is impossible for us to reproduce here these pictures, we are glad to give herewith an outline of Mr. Rigg's remarks made in connection with his demonstration.

While microscopic examination of thin slices of ores furnishes valuable indications as to their structure and to their probable behavior in the mill, this method requires the services of a man trained in the work. To get the results in such form that they can be readily understood and appreciated by the mill engineer and the mill foreman has not been an easy matter.

Plain microphotographs, depending only on differences of light and shade, are not easy to interpret by men not familiar with microscopic investigation, and in many cases the presence of a competent expert, provided with suitable equipment, is out of the question.

The Lumiere plate provides a means by which the indications of the microscope can be reproduced in their natural colors. Such matters as the fineness of the constituents of the ore, the shape of the different minerals, the manner in which they are interlocked, the nature of the gangue minerals and other particulars having a direct bearing on the problem of concentration, can be brought out in a manner which is both striking and instructive.

The slides shown by Mr. Rigg were intended to illustrate certain associations of minerals which are of importance as affecting the recovery in concentration.

Adhesion of valuable minerals to the gangue was shown by a slide representing a mica-schist carrying thin, wedge-shaped particles of blende and chalcopyrite intercalated between the plates of mica. On crushing, the valuable sulphides remained attached to the plates of mica and were carried by them into the tailings.

Losses due to parasitic inclusions were illustrated by a slice of actinolite rock, carrying blende as an interstitial mineral between the actinolite crystals, and quite capable of recovery, and also as parasitic crystals inside the actinolite crystals, and therefore destined to accompany the latter into the gangue.

An example of trouble due to fineness of grain was shown by a slide of calcite, permeated by hair-cracks and fine fissures filled with blende. The difference between the assay and the mill recovery with an ore of this type would be very great.

The application of polarized light to the demonstration of the constituents of an ore was illustrated by two slides of a calcite-willemite ore, one taken in ordinary light and the other in polarized light. The former simply showed an aggregate of colorless crystalline grains. The latter showed the calcite as various shades of grey, and the willemite in brilliant blues and pinks.

The contrast between examination of a hand specimen by the unaided eye and the indications of the microscope was shown by a specimen of argentite.

The hand specimen appeared to be solid argentite. The microscope showed a series of fine lamellæ of argentite and quartz. An ore of this kind would give a disappointing assay.

### Copper-Rich Kalchoids

A word unusual in scientific nomenclature is used by Prof. Samuel L. Hoyt in the title of his paper "On the Copper-Rich Kalchoids," read at the recent meeting of the British Institute of Metals. But kalchoids is a useful "omnibus" word, being employed to designate the ternary alloys of copper, tin and zinc as was first suggested by Thurston, and as such its use should extend.

In the paper under discussion Professor Hoyt gives the results of a prolonged research into the constitution of certain kalchoids rich in copper, the percentage of zinc and of tin never exceeding 50 and 30 respectively. From his microscopical analyses—and the paper is very liberally illustrated with upwards of 40 photo-micrographs in plate form—Professor Hoyt draws the general conclusion that the ternary alloys of copper-tin-zinc, up to the above-mentioned percentages, behave similarly to the binary alloys of copper-tin and copper-zinc. The liquidous surfaces, the limit of saturation of the alpha solid solution and the eutectoid line have been determined. The eutectoid surface was found to have a maximum near the middle corresponding to 66 per cent copper, 17 per cent tin, 17 per cent zinc and 590 deg. C. on the eutectoid line. This line showed the beta solid solutions to be isomorphous. Quenching from this line produced homogeneous solid solutions. The addition of tin to the copper-zinc alloys, or brasses, caused the visible breakdown of the beta solid solution. The amount of the tin necessary varied with the zinc content and with the rate of cooling through the critical range, thereby giving rise to abnormalities in the microstructure which are explained and well illustrated in the paper. An interesting point is that Professor Hoyt records the finding of a field off the alpha plus beta range in the bronzes in which two heating effects in the solid were observed.

The research is also noteworthy as showing the world-wide interest in the work of the (British) Institute of Metals, seeing that the paper has been prepared by a professor in the American University of Minnesota, who made his investigations in the Charlottenburg-Berlin Institute of Technology.

# A New High-Temperature Furnace

BY EDWIN F. NORTHRUP

For over two and a half years the writer has been conducting an experimental research upon the electrical conductivity of matter over a wide range of temperature above 0 deg. C. He early learned that the limit of his upper temperatures was greatly restricted if any furnace upon the market was to be used. It is true that vacuum furnaces of the Arsem type give as high temperatures as may be needed. But for the work in hand a very large furnace of this kind would be required to give a temperature of the necessary uniformity over a considerable length of the tubular space, and, furthermore, the difficulties in the way of feeding metal into the furnace and of bringing many leads out of a vacuum furnace were not easy to surmount. Furnaces operated with a hydrogen atmosphere to preserve the molybdenum or tungsten wire used as a winding from oxidation are unsuitable because hydrogen acts upon many of the molten metals. He was obliged, therefore, to develop a new and special type of furnace for the satisfactory prosecution of his research. This new type of furnace has had a development which has lasted over six months and it is now in a highly satisfactory state.

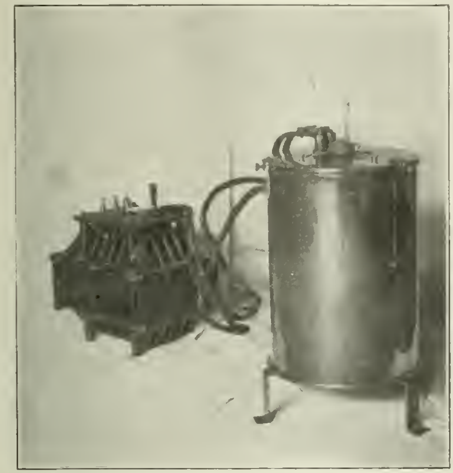

FIG. 1.—FURNACE AND TRANSFORMER

It is a laboratory furnace of the tubular type and is required to meet, in a very perfect way, the following conditions:

It must give a very uniform temperature in a tubular space about 12 in. long by 1⅞ in. in diameter.

The furnace must run for several hours above the melting point of platinum (1755 deg. C.) without being rapidly deteriorated.

The hot tubular zone must develop a pure CO atmosphere and the heating unit not be injured by the vapors of any molten metal or other material placed in the tubular space.

It is desirable and almost essential that all parts of the furnace, including the heating unit, should be quickly and easily replaceable. The life of the heating unit should be such that the expense for new heating units is not excessive.

It is evident that the one material for a heating unit which gives most promise of meeting these conditions is some form of carbon. The form of carbon adopted is pure Acheson graphite. This material has a low though very constant resistivity. As pointed out in a former article[*] its resistivity decreases about 9 or 10 per cent in the temperature range 20 deg. to 1500 deg. C. and not rapidly thereafter. There is probably no other material that has so constant a resistivity over so great a range of temperature. The resistivity being low, it is evident that the current must travel through a long length of the material and through a small cross section in order that the total resistance of the furnace may be sufficiently high to permit the use of relatively small currents. The furnace as made has a resistance when cold of 0.14 ohm. This result is obtained by the special manner in which the graphite heater-tube is cut. Furthermore the cuts are made in such a manner that the extreme ends of the tube develop exactly as much heat as the middle portion, and this permits great uniformity in the heating over a long length of tubular space. Such a tube when cut, if not properly protected, would be fragile mechanically and means had to be devised to make the heater-unit as a whole mechanically robust. This result is attained in a very effectual manner by carefully worked out details in the construction.

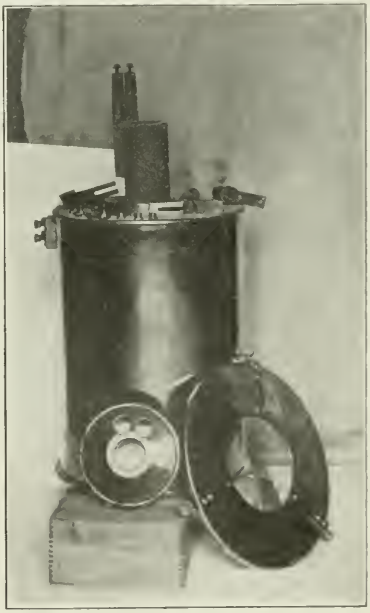

FIG. 2.—REMOVING A UNIT

Carbon or graphite, as is well known, is readily attacked by oxygen when above a red heat, and it was recognized that, if a unit were to last for many heatings, say forty or fifty, it must be effectually protected from oxidation. Perhaps the accomplishment of this result, without making use of a vacuum or by passing through the furnace any protecting gas, presented the greatest difficulty and expense. An electric furnace can only be thoroughly tested by destroying it, in which respect it is like a skyrocket. The result was finally attained by mounting the heater-unit in a molded refractory surrounded by what amounts to a hermetically sealed casing of monel metal. The CO atmosphere is developed by graphite. *which is not a part of the re-*

---

[*] "Some Effects of Temperature Upon the Resistance of Graphite and Carbon," METALLURGICAL AND CHEMICAL ENGINEERING, May, 1913.

*sistor*, and soon fills the furnace and effectually protects the graphite heater-unit for continued heating.

The terminals, which are always supposed to give trouble in furnaces which take a large current to operate, give no trouble and have a life longer than the unit itself. The furnace stands vertical and the two terminals project from the upper end of the tube at one side. They are covered with metal caps which can be quickly and easily removed.

The refractories in the furnace were selected, after much experimentation, to withstand a temperature of over 1800 deg. C. and to give at the same time the highest possible thermal insulation.

The tubular space in the furnace, which can be utilized for heating purposes, is 12 in. long by 1⅞ in. in diameter. The furnace casing is cylindrical in form and is made of monel metal, polished. It is 18¼ in. in length and 13 in. in diameter, on three legs 4½ in. high.

The furnace is so designed that in less than five minutes a graphite heater-unit can be withdrawn from the top of the case and a new one substituted. The metal terminal-caps, the refractories in the interior of the case and the top refractory piece, which forms the central portion of the top of the furnace, are all standard in size and easily and quickly interchangeable. In fact, perfect and easy interchangeability of all parts of the furnace is one of its special features.

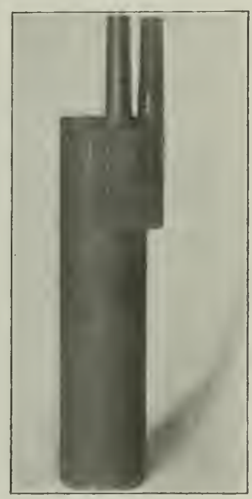

FIG. 3.—HEATER-UNIT

This furnace will operate, of course, on either direct or alternating current and calls for a maximum of 170 amp. at 23 volts. It is preferable to operate the furnace with a transformer of 4 kw capacity and such a transformer is a part of the outfit. The regulation of temperature is accomplished by the kilowatt input and this is varied by means of a switch which throws into circuit a varying number of turns upon the primary of the transformer. All the heat, therefore, is developed in the furnace where it is wanted instead of in rheostats where it is not wanted.

*The furnace cannot be burned out* with the transformer which is supplied with it. The heater-unit after repeated heatings will in time begin to gradually grow higher in resistance and when this resistance has become so great that with the 23 volts furnished by the transformer the required high temperature cannot be obtained, the old unit must be replaced by a new one. The writer cannot state definitely the life of one of these units, because this depends so largely upon the maximum temperature at which the furnace is operated. He believes, however, that it is a conservative statement to say that a unit may be heated to a temperature of 1500 deg. C forty or fifty times, and perhaps oftener. All other parts of the furnace are practically indestructible. He has had great satisfaction in using this furnace in feeling absolutely assured that in the midst of an important measurement the furnace will not burn out or otherwise fail to operate. Also, that nothing that he may put in the furnace, in the way of metal vapors, etc., will in any way injure it.

By the manner in which this furnace is constructed the heat insulation is the most perfect possible and the high temperatures reached are attained rather by a slow accumulation of heat, which only in part escapes as it is being developed, than by a brief and rapid input of a large amount of energy. In fact, a furnace may be constructed with very little heat insulation and a very high temperature be attained quickly with large power input, or it may be constructed with a large amount of heat insulation and the same high temperature be attained by the input of a small amount of power continued over a long time. For some classes of work the former and for other classes of work the latter type of furnace best serves the purpose. This furnace is of the latter type and consequently the watt input required to bring it to a high temperature is very small considering the size of the heating space, but this small watt input must be continued for a considerable time before the high temperature is reached. The furnace heats very slowly and cools very slowly. Slow cooling, for the work being done by the writer was desirable. The performance of the furnace in respect to rate of heating was measured several times and the accompanying curve gives a very good idea of how the furnace performs in respect to rate of heating.

The size of the furnace is that required by the writer in his work, but there is no reason why, with the same construction, the size may not be increased or decreased and the mounting be made horizontal as well as vertical.

The bottom of the tube when containing a crucible gives a perfect black body temperature and this makes the furnace admirably suited to the calibration of optical pyrometers.

Though this furnace was developed for his own researches it became apparent that it is so extremely useful for laboratory investigations that arrangements are being effected for its sale through the agency of the Arthur H. Thomas Company, of Philadelphia. The cost of development was large and no pains have been spared to perfect the furnace in workmanship and in minutest detail, and to use the best materials obtainable for its construction. The polished monel metal case makes the furnace a handsome and cleanly piece of laboratory apparatus. The outside of this case never exceeds 200 deg. C. when the interior of the furnace is at the temperature of melting platinum. It will not be an inexpensive piece of apparatus, but it is hoped a very useful one for

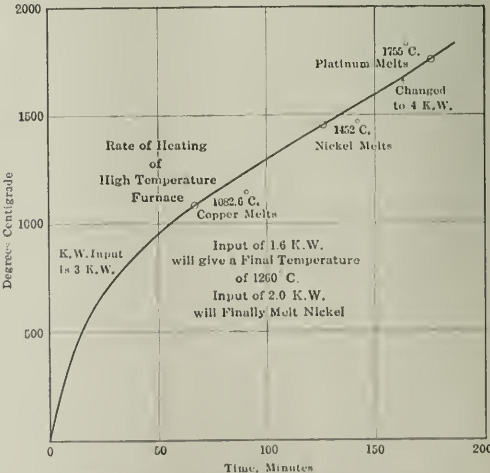

FIG. 4.—RESULTS OF TEST OF ELECTRIC FURNACE

those who have problems to solve in the temperature range 1000 deg. to 1700 deg. or possibly 1800 deg. C.

# Notes on Chemistry and Metallurgy in Great Britain

*(By Our London Correspondent)*

### The Institution of Electrical Engineers

### Research Announcements

The Research Committee of the Institution has announced its intention of conducting extensive investigations into questions concerning the nature and properties of insulating oils and of magnet steels. With regard to switch and transformer oils the subjects of research are classified as chemical, physical and chemico-physical.

In the chemical sections the questions arising include the relations between temperature and formation of sludge with exposure to the atmosphere; the laboratory tests to determine the production of sludge under abnormal conditions; and the means of preventing the formation of sludge; the absorption of moisture at various temperatures and the laying down of a standard as to what constitutes a dry oil, and what effect on specific resistance and dielectric strength is produced by increase of moisture; the investigation of the comparability of results obtained by the usual tests for acid, alkali, sulphur, resin and other impurities, and the standardization of such tests; the composition of the gases liberated when an arc is formed in the oil; the nature of the effect produced by traces of nitric acid or ozone by silent discharge at the terminals of high voltage transformers.

In the physical section the investigations will include the effect of time on formation of sludge and the changes in viscosity, specific gravity, flash-point, dielectric strength, and specific resistance accompanying the formation of sludge; the effect of circulating air over the surface of oil on its electrical properties and the formation of sludge; the temperature rise to which oils can be subjected without notable change in their physical properties; whether any standard practice is extant for ascertaining the relative thermal transference in switch and transformer oils, and what standard forms of apparatus should be employed for the purpose.

The chemico-physical points include the effect of specific gravity, viscosity and variation of temperature on the formation of sludge; and whether the amount of carbon produced by an arc in any oil varies with the temperature of the oil, or whether at a constant temperature the amount of carbon varies with the specific gravity and viscosity and other properties of the oils.

### Magnet Steels

In the research on magnet steels the following matters will be investigated: The relation in tungsten steels between percentage content of tungsten and coercive force when carbon content and temperature of quenching are constant; the effect in tungsten steel of manganese and silicon on the coercive force; the magnetic properties of vanadium and molybdenum steels (a) with varying content of V and Mo and the constant carbon, and (b) with constant V and Mo and varying carbon; the relation in high-carbon and in tungsten steels between the ductility or surface hardness and the residual magnetism; the best ratio of length to diameter for bar magnets of a standard tungsten steel; whether the transition temperature at which the steel regains its magnetism corresponds in high or medium-tungsten steels to Ar' or to Ar; the effect on the magnetic qualities of high-tungsten steels of brief preliminary heating to temperatures between 900° and 1,200°, which is known to lower the point of recalescence; a comparison of the values of the self-hardening steels of commerce and standard brands of tungsten steel in respect of remanence or of coercive force; the effect of procuring by prolonged heating in steam (as in the researches of Barus and Stronbal on carbon steel) on the remanence and coercive force of bar magnets of tungsten steel; the values of the coëfficients of self-demagnetization of horseshoe magnets and forms of magnets used in electricity meters; the values of the temperature coëfficients for matured magnets of nearly closed shape made of standard tungsten steel; whether and how the coercive force of matured bar magnets of standard tungsten steel depends on the intensity of the magnetizing field or on the time of magnetization; the magnetic properties of ferro-tungsten, ferro-vanadium and ferro-molybdenum when purified from carbon, silicon, manganese, sulphur and phosphorus; whether in a steel or pearlitic composition heated to 700° and very slowly cooled to 670° in a strong magnetic field any effect on the formation of the pearlitic structure will be produced; distortion as a result of quenching; and loss of magnetism as a result of vibration.

The arrangements for conducting both of these investigations are of a very complete character, and the co-operation of manufacturers and users has been secured to an extent which justifies the anticipation of practical results of more than academic value.

### Producer Gas from Wood Waste

Mr. G. E. Lygo recently read a paper before the Junior Institution of Engineers on the generation of gas from wood waste by means of suction plants of the Whitfield type. He said that the increased cost of coal had induced power users having waste combustible materials at their disposal to consider the installation of wood waste plants in spite of its higher cost as compared with an anthracite plant.

Every kind of woody material could be used, sawdust, cotton seeds, cocoanut shells, fibre, bark, surface peat, up to blocks of wood six inches across. The area of the generator depends on the nature and size of the waste, but as a rule it was about two and a half times the space requisite for coal. For wood in large pieces a deep fuel-bed was necessary to prevent air passing through and causing ignition of gas in the upper part of the generator; while some dense fuels, like sawdust, worked best with a comparatively shallow bed. It was not necessary to use a vaporizer, because the keeping down of the temperature in the combustion zone was not essential.

The plant must provide for the cooling and washing of the gas immediately on leaving the generator, lest the heavy tar and dust should choke the connecting pipe. The Whitfield anti-fluctuator was an ingenious arrangement which ensured a steady flow of gas, and the variation of pressure in the suction stroke seldom exceeded one inch of water, but in a plant without the anti-fluctuator a variation of six inches was often met with.

The calorific value of air-dried wood was about 6,000 B.Th.U. per lb. The consumption per b.h.p. was dependent on the content of moisture, which varied from 10 to 20 per cent in air-dried wood, to 30 to 50 per cent in freshly cut timber. Material containing excessive moisture must be dried until there was not more than 60 per cent, because with a higher moisture content the generator fire would not burn evenly.

The value of the gas produced was higher than that from anthracite, and was from 150 to 170 B.Th.U. per cubic foot as compared with 120 to 140 B.Th.U. for the coal gas.

Comparative costs of working were difficult to arrive at, much depending on whether the fuel could be used for other purposes, although generally it was almost valueless, but putting it at 10s. a ton it would equal anthracite at 25s a tone, and it then became a mere question of convenience. Where the wood waste was used to raise steam with a specially designed boiler the consumption per b.h.p. hour was from 6 lb to 10 lb., but with the producer the consumption was only 2½ to 3 lb. per b.h.p. hour. Experiments with an 84 b.h.p. engine driving a dynamo running at 105 volts gave 540 B.O.T. units for a consumption of 2,072 lb. of fuel, which equalled 3.83 lb. of fuel per kilowatt, with a Whitfield producer, for a ten hours' run.

In a certain factory the same amount of work was now being done with a producer plant, using wood waste alone, as had previously been done by a steam plant which consumed more than 500 tons of coal per annum in addition to the wood waste. His experience went to show that wood-working machinery in a factory made enough waste to produce all the power necessary to drive it when the waste was utilized in a producer, but with a steam plant such a result would rarely if ever be obtained.

### The Alby United Carbide Factories

The report of this company for the year ended on the 30th of June last goes a long way toward justifying the optimistic views of the company's prospects expressed by the chairman at the last annual meeting. The profit on the year's working amounted to £80,448, which affords a dividend of 12½ per cent on the ordinary shares.

For the year 1911-12 the profit was £72,792, and the dividend was 6 per cent, and for 1910-11 the profit amounted to £36,473 and provided a dividend of 5½ per cent. Preference shareholders had the option of converting into ordinary up to July 1, 1913, and they have availed themselves of it to such an extent that the capital account now shows £108,392 of fully-paid preference shares and £441,608 of fully-paid ordinaries.

The company holds 500,000 £1 shares in the recently formed Nitrogen Products and Carbide Company, Ltd., the total capital of which is £2,000,000, and which has absorbed the Nitrogen Fertilizers, Ltd., and the Nitrate Products, Ltd.; and has the controlling interest in the North-Western Cyanamide Company, Ltd., of London, in which it is directly or indirectly interested to the extent of 94,000 shares. Of the 500,000 shares in Nitrogen Products, Ltd., 259,620 were acquired by purchase, and the last balance sheet shows an uncalled liability of £244,620 in respect of these.

### Engineering Imports and Exports

The returns issued by the Board of Trade for the ten months ended on the 30th November show increases in both imports and exports of all the chief classes of engineering materials and products, although the figures for November exhibit a general decline in exports as compared with the corresponding periods of last year. For the ten months the imports of iron and steel, including manufactures, amounted to £12,558,389, and the exports to £45,634,880, the respective increases being £2,068,367 and £6,110,923. Imports of other metals, including manufactures, totaled £27,154,415, an increase of £1,595,432; and exports reached £11,128,323, an increase of £1,113,727. In machinery the imports are valued at £6,101,150, an increase of £455,327, and the exports are put at £30,760,860, an improvement of £3,258,605. New ships were imported to the value of £29,101, an increase of £2,449; whilst exports worth £10,142,785 show a rise of £4,468,843.

For the month of November alone imports of iron and steel increased £108,674, but exports decreased £302,098; imports of other metals fell £367,515, and exports also fell by £174,678; electrical goods showed a rise of £7,035 in imports, but a decline of £189,816 in exports; imports of machinery increased £6,545, and exports decreased £174,574; imports of new ships rose £726, whilst exports decreased by £237,924.

### Market Prices

*November*, 1913

| | £ s. d. |

---

**The Arizona Copper Co.** produced only 1400 tons of copper during the month of November, 1913. Considerable progress has been made in getting the new furnaces into operation.

**A new metallic alloy** of iron, manganese, aluminium and nickel has recently been patented by Walter Rubel, of Berlin, Germany. The metals are melted together in proportions corresponding to the multiples of their atomic weights expressed in the formula $4(FeNi) + 8Al$ Mn. The alloy is said to be useful as an addition to copper and aluminium to form a bronze.

# Utilization of Wood Waste.

## IV—BATH PROCESSES.

BY JOHN E. TEEPLE, PH.D.

Among the various methods of utilizing waste wood or obtaining valuable byproducts from wood, we have mentioned "Bath Processes." It might be difficult to differentiate encyclopediacally between a bath process and a solvent process, or to determine the particular point where a bath ceases to be a bath and becomes a solvent. In practice, however, the two systems have been entirely distinct, have developed independently and worked on entirely different lines. Broadly speaking, the bath has always been non-volatile, and the solvent volatile. The bath has been employed on cord wood and the solvent on disintegrated wood.

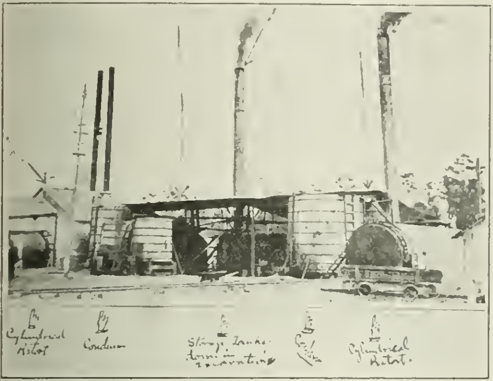

FIG. 1.—GENERAL VIEW OF BATH PROCESS PLANT

The first developments of the bath process were in North Carolina about ten years ago. Two plants of very considerable size were built and later remodeled, but neither of them has operated for several years. The investment here considerably exceeded one hundred thousand dollars. Operations were presumably conducted under the Weed (1905) and the Mackenzie patents.

The next development was in South Carolina where an experimental plant was built to operate under the Davis (1904 and 1906) patents, but by 1907 it had ceased to develop. The next step was the construction of a plant in Georgia operating under the Pope patents. This plant at the present moment is in the hands of a receiver, with outsanding stocks and bonds said to amount to many hundred thousand dollars.

The final progress of the idea was to Florida, where the largest of all the bath process plants was built and started operation in 1911. This last plant also ceased operations during this present year, so that now none of the five attempts is a going concern. On the other hand, conditions and prices that have existed in naval stores this year are unusual, and it may well be that some one or more of these plants under more favorable circumstances might resume operations.

The fundamental idea in all these plants was the use of a liquid bath in actual contact with the wood to remove valuable constituents of the wood. The first bath used was melted rosin. Rosin of the common grades melts around 120 deg. C., and when in a liquid state can be handled readily by pumps through pipes. Details of the process differed of course in the several plants and in the same plant at different times. In one method the wood in four-foot lengths was loaded into cars made of latticed iron and each holding nearly a cord. Ten of these cars were then run into a cylindrical retort and the door closed. In some cases the sides of the retort interiorly were squared up with cement so that the rectangular cars used would occupy nearly all the available space inside the retort. In one case the retorts were concrete instead of steel.

The rosin bath kept liquid in large vats or storage tanks was then pumped through a system of coils used as a heater, and thence into the bottom of the retort at a temperature of, say, 190 deg. C. As pumping continued the bath came into actual contact with the wood, and heated it to a point where the mixed turpentine water and oils in the wood vaporized and left the wood. The bath overflowed into a vaporizing chamber where with the injection of steam, if necessary, the volatile parts were removed and then condensed. Thence the bath returned to the pumps and heaters to continue its circuit until the wood was sufficiently extracted, usually about eight hours. At the end of the extraction the bath was removed from the retort, leaving the wood freed from most of its volatile constituents, still in cordwood shape, still containing its rosin and suitable for fuel or for destructive distillation.

It was assumed in the early stages that the rosin bath would increase by extracting rosin from the wood, so that rosin could be marketed from time to time. Experience, however, usually showed the contrary, and it was more often necessary to replenish the bath with purchased rosin. It will be seen that the operation was continuous during any single distillation, and considerable quantities of rosin were in circulation in the retort, pipes, pump and heater.

A moment's consideration will suggest at once that in any accident causing stoppage of the circulation and cooling of the bath the rosin would "freeze," and there would be heavy bills to pay and no pitch hot. Such an accident occurred more than once in spite of precautions and duplication of machinery. A further disadvantage was the heavy wear on the heating pipes causing leaks. If these leaks occurred inside where they were hidden from view the rosin bath could leak away and serve as fuel for the heater for long periods before it was detected. If the leak occurred in the open there was serious danger to the plant from fire.

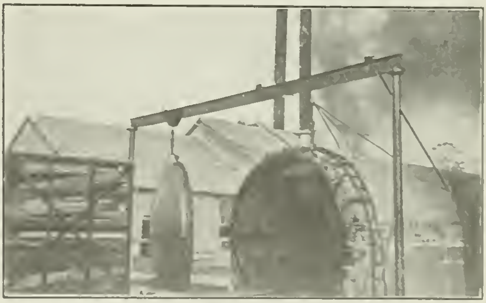

FIG. 2.—CYLINDRICAL RETORT AND CAR OF WOOD IN BATH PROCESS PLANT

As to yields, the claims as usual were liable to be high. The tendency seems to be the same as it is with an applicant for a patent; claim everything in sight, because you certainly will not get credit for anything you don't claim. The ordinary statement given is that 1000 pounds of wood gave 7½ gallons of oil, half of this being turpentine and the remainder oxidized and hydrated derivatives grouped as pine oils, and rosin oils and other decomposition products of the rosin bath caused by the high temperature.

It seems worth while to insist again though, that this whole question of yields is a purely relative one, depending on the wood. You can't get 10 gallons of turpentine out of 8-gallon wood, and one dosen't deserve any particular credit for getting 12 gallons out of 18-gallon wood. The fact that you squeezed two pounds of water out of a sponge while I only squeezed one pound out of another sponge doesn't entitle you to crow over the superority of your squeezing process till we know a little more about the relative capacity and humidity of the two sponges.

I have seen a plant working by the steam process get an average of 7 to 9 gallons of turpentine from its wood day after day, and I have seen the same plant without other change than a little intelligence and forcefulness behind the men in the woods, produce 14 gallons of turpentine per cord day after day, with no material increase in the cost of the wood. Until we are ready to state yields in terms of percentage recovery of all the turpentine, oils and rosin in the wood we can draw very few conclusions from figures excepting as post mortem exhibits to show why the plant died.

In any case the bath processes made reasonable recoveries of turpentine and oils and had over half of their wood left after furnishing fuel to their rosin baths. The last two plants constructed erected destructive distillation plants of the car and oven type to char this wood and obtain tar, charcoal, various oils and some low-grade turpentine. This was a logical step, but apparently more was required to save them from financial difficulty. At any rate none are now in operation. To obviate the difficulties of using a rosin bath many mixed baths were tried, using tar, tar oils, creosote oils, pine oils, pitch, etc., in various proportions with considerable success. It seems reasonable to suppose that under favorable conditions and good management some of these plants may still be a factor in developing the industry.

## International Electrical Congress

### San Francisco, 1915

The International *Electrical* Congress is to be held at San Francisco, September 13 to 18, 1915, under the auspices of the American Institute of Electrical Engineers by authority of the International Electrotechnical Commission, and during the Panama-Pacific International Exposition. Dr. C. P. Steinmetz has accepted the Honorary Presidency of the Congress. The deliberations of the Congress will be divided among twelve sections which will deal exclusively with electricity and electrical practice. There will probably be about 250 papers.

Attention is drawn to the distinction between this Electrical Congress and the International *Engineering* Congress which will be held at San Francisco during the week immediately following the electrical congress. The engineering congress is supported by the Societies of Civil, Mechanical and Marine Engineers and by the Institutes of Mining and Electrical Engineers, as well as by prominent Pacific Coast engineers who are actively engaged in organizing it. This Congress will deal with engineering in a general sense, electrical engineering subjects being limited to one of the eleven sections which will include about twelve papers, treating more particularly applications of electricity in engineering work.

The American Electrochemical Society will hold a meeting in connection with the Electrochemical Section of the International Electrical Congress.

## Notes on Open Up Ozonator Designs

BY A. VOSMAER, PH.D.

For the sake of convenience in handling the subject, ozonators may be classified under two essentially different headings, viz.: those which are based upon the principle of using some solid dielectric between the dischargers, and those which do not make use of any solid dielectric for this purpose. The first named have been the first in the field; they were for a short time threatened to be superseded by the second named class; the result, however, has been that they stand now in the front, stronger than ever.

Although the no-dielectric class has been forced to give way to the other, still it is of interest to discuss the former because it not only gives a better insight into the matter of ozonators in general, but will also cause a better appreciation of the dielectric system, if one knows why the latter has won the victory.

Bearing in mind that the object of discussing the non-dielectric system is to bring forth the advantage and value of the other class, it is logical first to deal with the former.

### 1. Ozonators Without Solid Dielectric Between Electrodes

From the year 1857, when Werner von Siemens made the first commercial ozonator, up to 1894 when Schneller took out his patent, the general thought prevailed that the use of a solid dielectric was essential to having the brush discharge with the exclusion of spark and arc.

Schneller was the first to prove that this is not the case, and it is interesting to note how a totally wrong reasoning led him to an arrangement that actually did work, though poorly.

Schneller assumed that the rôle of the dielectric was that of a high resistance in the path of the electricity and argued that as this was so we can as well place it somewhere else in the circuit and use some other material for it.

So he arranged his circuit in such a way that one of the terminals of the high—very high—tension transformer was connected to what he called a specific resistance, and from there to the sharp pointed discharger, discharging against a flat surface which was connected to the other terminal of the transformer and for the sake of convenience also to the earth.

We shall come back to this arrangement later on. Whatever we may think of the idea, it certainly proved that a solid dielectric between the dischargers was not an essential point in the art.

The second way of doing away with a dielectric (we shall henceforth thus abbreviate the expression of a solid dielectric between the electrodes) was to have recourse to high-frequency currents. This was Tesla's method.

The third method was Otto's, based upon the principle that an arc when drawn out will thereby be extinguished. Otto used revolving electrodes, that is to say, one revolving electrode inside of one fixed electrode.

When I saw Schneller's system at work and on the one hand was thereby convinced that the dielectric is not a *conditio sine qua non* for the maintenance of brush discharges, but also convinced, on the other hand, that Schneller's method was based upon a wrong assumption, I began to investigate the subject. After a good many years of experimental research and careful investigation I finally found that the whole secret of the matter lies in a true harmony between the different items that enter into consideration—voltage, polar distance, shape and size of each of the dischargers proper, kind of current supplied, etc.

If there be true harmony between all of these, then and only then is it possible to have brush discharges and nothing but these going on and on any scale required.

So I got my first patent in the year 1897, but in actual practice it soon turned out that perfect harmony once established does not always stay on. For instance, some alteration in the speed of the dynamo will give rise to a change in voltage which may be large enough to endanger the state of equilibrium. That is the reason why I was very fortunate in finding an automatic device that absolutely controlled the system. I will discuss this later.

These four are the systems which work without a dielectric and are thus essentially differentiated from the dielectric system and also from each other. There are some interesting scientitfic details involved in these different systems which may be discussed, not on account of their commercial interest, since none of these systems has any commercial interest at all, but for the reason that they are of value for understanding the history and the development of the dielectric system.

### (a) The Schneller System

Fig. 1 gives a diagrammatic sketch of Schneller's idea. Tr is the transformer, E the earth connection, O the ozonator and G the "specific resistance," as he calls them. This was a glass tube filled with about 80 per cent. glycerine the apparent ohmic resistance of which amounted to about 20 million ohms. In his large ozonizer (2 K W) there were 75 of these tubes connected in parallel to as many double discharging combs. The secondary tension was about 50,000 to 60,000 volts. All these figures refer to the original Tindal plant in Holland.

The actual working of that plant aroused in 1895 quite a stir. A great many scientists came to see this wonder, and full credit must be given to Tindal, who owned the Schneller patents, for having been the first to demonstrate on a fairly large scale the possibility of the sterilization of drinking water by ozone.

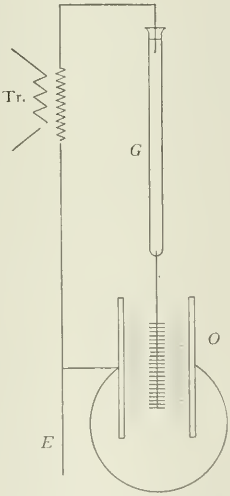

FIG. 1.—SCHNELLER SYSTEM

The first electrical question that at once comes up is this: Why did he use 75 tubes of 20 million ohms each in parallel instead of one of equivalent value? And the next question is this: Can that liquid resistance be supplanted by a solid one?

The inventor himself was never able to answer these questions and it has taken me considerable time to find out that said specific resistances did not work as such and could not be replaced by an ordinary metallic resistance, and that tubes filled with glycerine do not act through their considerable ohmic resistance but actually act as a pseudo-capacity of large value. If one inserts a condenser of large capacity in the system in series, then one obtains exactly the same result. The voltaic arc will not be checked *unless* the voltage be very carefully watched, so that it would never rise above a certain limit.

I remember when working with Tindal that to my great surprise they were very careful about the voltage. A man was watching it continuously. My surprise was due to the fact that the patentee claimed to be sure of brush discharges and to keep out other kinds of discharges.

*A posteriori* it is all very clear, but at that time it was called a "wonder." The mistake of the Tindal people was that they did not work on a scientific basis. They did not know actually what they were doing, although the performance, being pioneer work, should be given full credit. It is so much easier to criticize afterwards than to invent before the realization of an idea.

In 1898 the same Tindal and Schneller patented an ozonator based upon the principle of the use of a dielectric, viz.: a layer of enamel, and had the shrewdness not to call this a dielectric but a means of obtaining a smooth surface.

It is a pity that the financial generosity of Tindal has not resulted in a better system. He was the man to whom we are all indebted for the knowledge of the wonderful effect of ozone on water. He gave the impetus for working out this scientific problem on a large commercial scale. Tindal died several years ago.

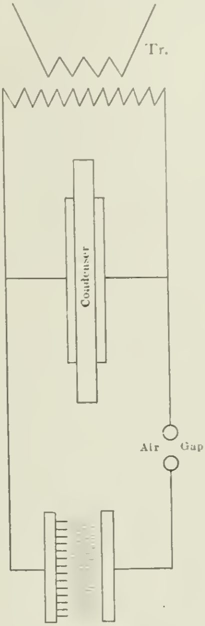

FIG. 2.—TESLA SYSTEM

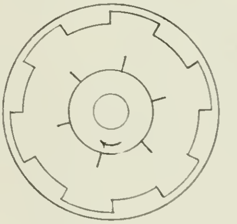
### (b) The Tesla System

This system is too well known to need much comment. The special circuit comprising a condenser in shunt and a spark gap in series is familiar to all. The most strikingly beautiful brush discharges can thereby be obtained now without the least fear of arcing and have been enjoyed as a grand sight by many, but for the purpose of ozone making there is one objection to it. The yield of ozone per kw-hour is far too low in comparison to other systems, and this fact has prevented any actual use of it on large scale.

The diagrammatical sketch, Fig. 2, shows the principle.



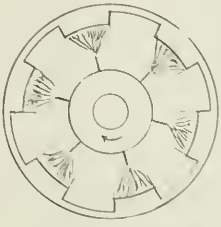


FIG. 3.—OTTO SYSTEM

### (c) The Otto System

If Otto, when he applied for his revolving-electrode patent, had known that it is better to prevent than to cure, and that prevention of arcs is quite possible when there is harmony between the revolving speed and the periodicity of the current, his system might have been an improvement. But as it is, not much benefit is to be derived from the arrangement.

Fig. 3 shows the principle in sketch. It is evident that there can only be here a question of cutting off arcs after they have been established, instead of making their appearance impossible. Had he claimed to turn the revolving electrode in synchronism with the alternating current, then the arc could have been avoided.

### (d) The Vosmaer System

If, in order to obtain brush discharges and nothing but these, it is not necessary to have recourse to high-frequency current, or to the intercalation of a very high resistance, nor to have one or both electrodes in motion, what, then, is required to have things go as desired? This is the vital question. It is very easy to answer, however, because actual experiment on a large scale—up to 10 kw—has shown me that nothing else is required than to understand the subject thoroughly and on this basis to establish true harmony between the different electrical apparatuses.

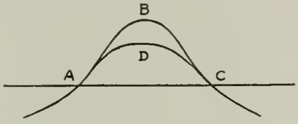

FIG. 4.—VOLTAGE WAVE CURVES

Remember that the spark is a disruptive oscillatory discharge, requiring a high density of electric charge at the place of discharge—hence the use of large spheres for this purpose.

Remember, too, that the voltaic arc has conditions of its own, that it represents the low-tension, high current-density discharge, started by actual transport of solid matter and continued by the conduction of gaseous matter at very high temperature, that the arc is started at small polar distance and can then be drawn out.

All these conditions are not fulfilled when one has a needle-pointed electrode, spaced at a distance of say half an inch from the other pole; when the potential difference is gradually increased there comes a moment when a brush is formed. If the voltage is kept at that value or a little higher it is possible to maintain the brush.[1] In my 2-kw. ozonator I could arrange it so that all this energy was taken up by brushes, no less than 240,000 needles being used in the apparatus.

The flow of electricity is such an even one, so smooth and regular, that no interruption need be feared, unless —and that is the point—there is a reason for it in the form of rise in voltage or particles of dust or metal playing the rôle of a solid conveyor from pole to pole.

The brush discharge from an alternating current supply is an intermittent one, in the first place because the points do not discharge unless they are positive; in the second place because the voltage is a wave and a certain minimum voltage is essential to discharge.

If the actual voltage wave be considered to be sinusoidal, the actual discharge voltage wave will be something like Fig. 4 shows, because the regular flow-off of electricity will prevent the tension to reach its maximum value.

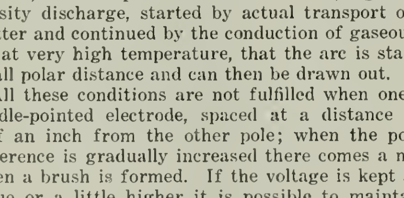

FIG. 5.—VOSMAER OZONATOR CONNECTIONS

Thus theoretically there is no difficulty in maintaining a regular brush discharge from properly shaped electrodes at proper distance, but in actual practical work it is hardly possible to realize the condition of absolute constant voltage and absolute dust-free air, and some means had to be provided for guarding against accidental circumstances.

That automatic safety arrangement was as follows:

In the circuit from the transformer secondary ends to the ozonator electrodes there is a condenser in shunt, and a reactance coil in series (see Fig. 5). The object of this arrangement is that, through the combined effect of capacity and self-induction, one in shunt and the other in series, the original transformer tension is raised to a considerable extent, in fact multiplied by any number up to 15. Perhaps that is not the limit, though it was the limit in our experiments.

In actual work no such intense raise is wanted, my regular work having been done with a raise of not more than from 7700 to 10,000 volts. By this I want to say that the primary tension was 110 volts and the ratio of transformation being 70, that would give 7700 volts at the secondary terminals, but the special way of connecting up (patented by me and my partner, Dr. Lebret, in the year 1902) causes the tension to be 10,000 volts.

This raise of tension, however, also depends, as regards its magnitude, on the value of the resistance at O. As soon as this drops, say on account of a spark caused by a particle of metal, then said raise in tension drops also, and by so doing ends the spark; in this way the spark is killed by its birth or even before that, because even the *tendency* to start sparking is *checked* by the special circuit.

Arcing is an absolute impossibility, as was repeatedly demonstrated when raising the primary voltage on purpose, say to some 20 per cent. The way of connecting up is altogether against the nature of voltaic arcs.[1]

It is useless to tell of all the technical difficulties that had to be surmounted before a 20-kw unit could be made. It worked beautifully. Occasional sparks were promptly extinguished. But my system for which I had been working so hard had to suffer the same fate as all the others. It had to give way to a better one, better taken in the sense of efficiency as regards output of ozone per kw-hour.

### II. Ozonators With a Solid Dielectric Between Electrodes

### (a) The Dielectric

The dielectric in an ozonator is subjected not only to the electric stress put on it, which, by the way, is a very severe one, but also to the heating effect of the discharge. We remind the reader that no more than 10 per cent. of the electrical energy is converted into ozone,[2] the rest is wasted as heat. Then there is the destructive effect of the ozone and the mechanical effect of the continual bombardment of charged molecules of gas.

There are not many materials that will stand all this. In fact there is but one at the present moment, viz., glass.

Nearly all the insulators made of or containing organic matter fail on account of the rapid destruction of it by the ozone generated, this being more especially the case with all those which contain rubber.

There are several lacquers that are not oxidized by ozone, for instance, shellac, and it might be that use could be made of this material. However, it is worth knowing that all laminated materials, such as micanite, shellaced paper, etc., cannot be used on account of their liability to peel off when subjected to the discharge and heat.

Celluloid cannot be used on account of the danger of taking fire. Vulcan fiber and fibrous material like it is no good at all because the discharge will "eat" its way through.

---

[1] See the Brush Discharge, by A. Vosmaer, Met. & Chem. Engineering, Nov., 1913.

[2] See Ozone, by A. Vosmaer, Met. & Chem. Engineering, Dec., 1913.

Amongst the minerals there are but few that can be had in a convenient shape. But slate and mica have been in use. The first, however, is by far too irregular in insulating properties; the second is an excellent insulator, but its peculiar property of being a highly laminated structure excludes its use for the purpose in mind.

That leaves one more group, viz., glass, enamel, porcelain and quartz. Enamel is a kind of leadglass containing a considerable amount of metallic oxides. It is a very poor insulator, very sensitive to rise of temperature, very seldom a homogeneous mixture, and no good at all for the purpose. Strange to say, porcelain does not give satisfaction at all; when used in ozonators for a dielectric it very soon gives way; small perforations are set up within shortly, and that, of course, results in the voltaic arc which means ruin to the ozonator.

I believe this strange behavior of a material so highly appreciated in other branches of electrical engineering is due to the fact that after all porcelain is not a material of homogeneous composition. Quartz and its kindred substitutes, fails for the same reason. Its fusion has not been a complete one. The molecular cohesion is rather poor. It is very brittle. But it may be and we might even say it is possible that before long, properly fused quartz can be obtained in large masses and in convenient size and form.

Thus really nothing is left but glass. Now, glass is a collective name for a large class of material. There is such a variety in quality, properties and make that some classification has to be made.

The so-called lead glass does not possess the properties sought for. Of the sodium and potassium-lime glasses the latter is to be preferred; that is the kind known as hard glass, manufactured as a specialty in Bohemia. It is a flint glass of good composition.

Glass has the advantage over several other materials that it can be had in almost any conceivable shape, of any size and any weight, up to a certain limit, of course—which limit is never reached in ozonators, however.

A great many failures of ozonators are due to the unsuitable quality of the glass used as dielectric. Many laymen who also are ozonator inventors—and there are many of these—think glass is glass and they take the cheapest kind they can get.

But the manufacture of glass has become quite a scientific art and it is very probable that when the demand comes, glass manufacturers will be able to supply a kind of glass that just suits the purpose to a nicety.

As the situation is now, there is always some danger, because glass is a treacherous material. It may look well outside, but the inside may be largely overstrained, internal stresses being difficult to overcome. For the present the best policy seems to be to try all samples and keep the good ones.

The dielectric strength of glass varies between so wide limits and depends on so many circumstances that definite figures cannot be given. For one millimeter of thickness it may be between 10,000 and 70,000 volts. It largely depends on the shape and size of the electrodes used, on the kind of current, viz., direct or alternating current, on periodicity and very largely on the temperature, so that the variations are too large to give an average figure.

The effect of temperature on the dielectric strength is a very marked one. Glass is a regular electrolytic conductor at high temperatures, and that is one of the traps for ozonators. If through excessive strain the dielectric should become too hot it gives way through simple conduction, thereby establishing the arc discharge.

The conductivity of insulators is a very fascinating subject to discuss, but would lead us too far away from our subject.

Let it be sufficient for the present to state that the right kind of glass suits the purpose of its use in ozonators as a dielectric very well if all conditions are judiciously chosen and thought over and checked by experience.

### (b) Principle of Arrangement

In Fig. 6 are sketched more or less different ways of placing the dielectric showing in (*a*) one glass dielectric and two air spaces, in (*b*) we see the omission of one of the two air spaces, in (*c*) we have one air space and two glass dielectrics, while (*d*) is merely a change in construction. Now these different ways can be combined to different shapes of electrodes, and that gives all the possibilities—not very many, indeed.

Details of construction may, however, bring about a great change in efficiency. For example, if ozone of great concentration be wanted, then there should be a great amount of electrical energy discharging in a small space. This, however, also means a great amount of heat, and it is absolutely necessary to carry away this heat through effective cooling of electrodes and dielectric, and this is a condition not so very easily fulfilled.

It is immaterial, as regards the principle, whether the glass be flat or curved. This means that it makes no difference whether the ozonator is built up of plates or of tubes. Some people have their reasons for preferring the plain plate, others again prefer the tube. Some are using all sorts of fancy shapes of electrodes, others believe in simplicity.

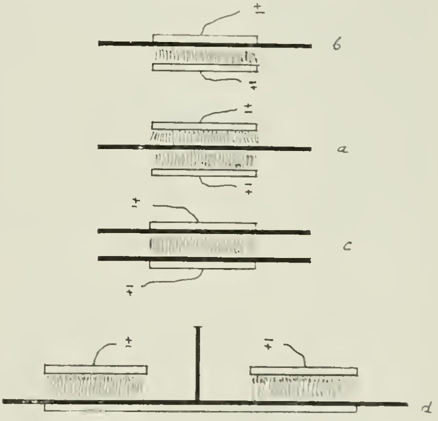

FIG. 6.—DIFFERENT ARRANGEMENTS OF DIELECTRIC

There is much less difficulty in constructing an ozonator for low concentration than there is for high concentration. For ventilating purposes, where a very low concentration is wanted, there is no need of artificial cooling, since the air passing through takes care of that.

Again, in small-size ozonators for individual use, the yield of ozone per kw-hour is of far less importance than the simplicity of the apparatus, so that, after all, though there is not much variety in the principle underlying different ozonators, there is quite enough variety in the several makes.

### (c) Some Ozonators

#### THE SIEMENS OZONATOR

Werner Siemens was the first who constructed ozonators on a commercial basis, and after several improvements the Siemens tube still holds a prominent place. The first trial was made with an apparatus built up of two coaxial glass tubes, either coated respectively inside and outside with tinfoil and partly filled with acidulated water.

Here we have a case of two dielectrics and one air space.

Later on use was made of mica tubes, which, of course, did not give satisfaction. Then the firm developed an apparatus built up of large plate glass dielectrics, but after in actual service it had been proved that the glass tube either makes a better apparatus or gives better results, the later Siemens ozonators are now substantially built glass apparatus, six of them joined in one casing. They consist of one electrode of metal, an air space, one glass cylinder as solid dielectric, then a liquid electrode, which serves the purpose of cooling at the same time, as shown in Fig. 7.

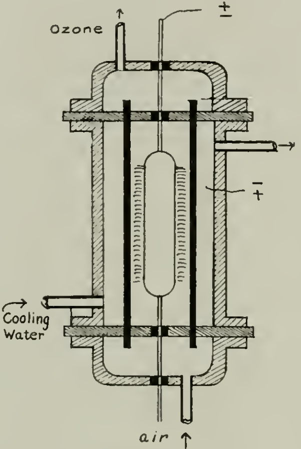

FIG. 7.—SIEMENS OZONATOR

We are all familiar with the general appearance of this type of ozonator, which has been published so many times on account of its being tested on a large scale and found to be efficient and reliable. The large European ozone plants are using this type of ozonator, which proves its fitness to do the work.

We may consider the Siemens tube to be the outcome of the original Berthelot laboratory apparatus.

### THE GIRARD OZONATOR

The original Berthelot tube for laboratory use, modified so as to become an industrial ozonator, is what is the Gerard tube, the most prominent feature of which is the high output in ozone per kw.-hour.

The principle is that of Fig. 8, showing two dielectrics, one air space and two metallic electrodes, one of which is energetically cooled with oil. It seems that this arrangement is the best for producing high concentrations of ozone, although it is difficult to understand why it should be superior to the one-dielectric system.

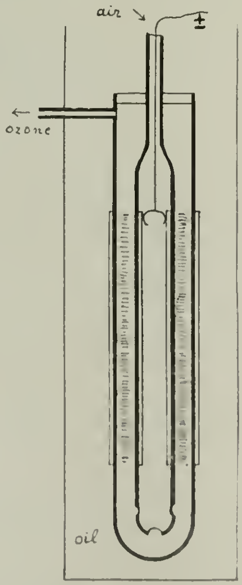

FIG. 8.—GERARD OZONATOR

### THE OTTO OZONATOR

On finding that after all the rotating electrodes did not prevent the arc, Otto finally also took up the dielectric system, and kept his revolving electrodes, although the advantage of this moving part is not very obvious.

### THE VOHR OZONATOR

Realizing the difficulty of obtaining a glass that will suit the purpose, and realizing that such is still more so in the case of tubes or cylinders, the Hudson Ozone Machine Company has arranged an ozonator in the style of a grid. It certainly has the advantage of cheapness as regards the dielectric, which in this case consists of nothing but strips of glass, easy to replace in case of damage and made of choice glass.

In the accompanying sketch, Fig. 9, its simplicity shows itself clearly. The electrodes discharge from both sides. As there is no artificial cooling the current density per surface of electrode has to be kept low so as not to cause a dangerous rise of temperature.

The grids are made in units and can be joined in a suitable casing. The system does not allow of obtaining extremely high concentrations, but as said repeatedly there hardly is a need for those very high concentrations. Personally I have done all the work with a concentration as low as one or a little over one gram per cubic meter, and that is quite enough, except in some very special cases. The secret of the use of low-concentration ozone lies in the knowledge of exactly the best way of application, and that is a matter of experience.

There are several other ozonators on the market yet, and we could lengthen this article by enumerating and describing them from the patents, but that is not the object of this article. On the contrary, I have been endeavoring to condense it as much as consistent with good understanding. Moreover, as it is only in details that different makes differ, it would be of little interest to repeat again what has already been said so often.

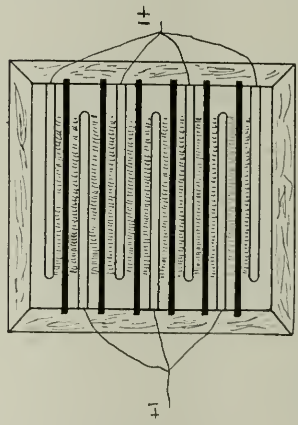

FIG. 9.—VOHR OZONATOR

I wish to conclude this by reminding the reader and prospective user of ozonators that at present they can be had for any concentration up to say 30 grams of ozone per cubic meter and for any quantity.

The Gerard and the Siemens apparatus seem particularly adapted for the manufacture of high-concentration ozone, the Vohr suits the purpose of lower concentration. Just what concentration is wanted for a given purpose cannot be said in a few words. The output per kw-hour is less for a high than it is for a low concentration so that it would be bad policy to first make a highly concentrated ozone and dilute it by mixing with more air. Most of the present applications of ozone can be successfully carried out with a concentration of about one gram per cubic meter of air; some require 3 to 5 grams, some no more than one milligram (see the article in the December number).

The vital point for an ozonator to do its work and to do it satisfactorily is that it shall not be run to its utmost capacity. It is better to stay a long way off that, because the more energy is used per unit of surface the higher the concentration and the higher the yield, *but* at the risk of a breakdown.

A common mistake of most people who start working on ozone is to push the discharge. At its best, this method gives high figures for output but does great damage to the reliability of the apparatus. Experience must tell the operator the safe limit for continuous operation.

No more than 5% as a rule and never more than 10% of the energy is usefully employed in the conversion to ozone, the rest is wasted as heat and should be taken care of accordingly.

By way of comparison it may be said that the original Schneller system gave 4 grams of ozone per kw-hour, his latter system gave 7, the Vosmer system gave 12, the Siemens 30, the Gerard is said to give 50 to 80. These figures must not be looked upon as of much importance. They are liable to change according to circumstances and are not strictly comparable.

It is a mistake to look only for high output per kw-hour. There are many other items of as much or sometimes even of more importance, for instance, reliability, constancy, cost of installation, cost of maintenance, and many others.

From an electrical standpoint ozonators may be looked upon as condensers of enormous capacity, both pseudo and real, and as this is a rather unusual load for an alternator, the phase difference should be corrected by some self-induction so as to get the full power out of the alternator. This point is generally overlooked. We are used to look out for self-induction, but capacity is just as bad. It is less common and hence less thought of. We all know of the Ferranti effect caused by the capacity of long cables but here we have a case of extremely high capacity not met with in the ordinary daily practice.

Ozonators are always run in parallel and it is safe to group a number to be fed by one transformer so as to be free in making repairs or changes without interfering with the rest of the machines.

The fact that glass has to be used for ozonators and that it is liable to break, limits the size of a single apparatus to a convenient size. Hence their great number in large plants such as are now in very successful operation in Europe.

Those who never worked in the field of ozonators usually wonder why it is not practical to place a large number of them close together and have one casing for them. Well, the reason is that apart from the fact that one has to provide for a large cooling surface, there is another objection to doing so, that is their individual electric fields. These are obnoxious in a terrible way. These individual electric fields are rather hard to calculate and not so easy to shield off as one might expect from ordinary work.

It is all a question of experience to be able to arrange matters in a satisfactory way, here as in any other branch of applied science, but here especially, because rather unusual factors are here encountered. But the fact that in Europe many very large plants do operate satisfactorily indicates that experts have overcome all the difficulties, and it is to be expected that within the near future ozonators will be as common apparatus as electric furnaces.

---

**The United States mineral production** for 1912 as finally announced by the Geological Survey, was the greatest in the history of the country, exceeding even that of 1907, which has been considered the boom year. The total value of production was two and a quarter billion dollars.

**Montana leads other states** in the production of precious stones, this supremacy being due to the mining of sapphire. The value of these gems produced in 1912 was $200,585. The total value of metal production of Montana in 1912 was $70,000,000.

# History of Electric Furnaces

BY WOOLSEY MCA. JOHNSON AND GEORGE N. SIEGER

The electric furnace can be described as a short circuit under control. It can also be defined as a metallurgical apparatus for the utilization of the thermal effects of the electric current for an industrial purpose. Electrical energy is turned into "commercial energy," or something is given "form-value" by the electric furnace. The thing that is the driving force of the industrial operation is the electric current and the thing by which the energy is usefully applied is the electric furnace.

Now so long as power was derived from some primary electric battery no practical effect was attained for the reason that it was too difficult to get power enough to do much work in the electric furnace, even though the cost was not at all considered. Later the dynamo was practicalized by Edison, Siemens and others. When this was done some adequate source of power was at hand and the experimenter having a generator upon which he could rely, could turn his attention to the electric furnace.

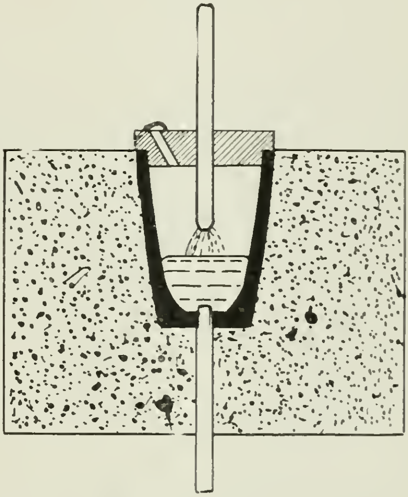

FIG. 1.—VERTICAL ARC TYPE OF ELECTRIC FURNACE

Accordingly, prior to 1876 we find but little accomplished in the electric furnace save of purely scientific interest. Sir Humphrey Davy—in 1800—was alive to the possibilities of electrically generated heat and built a small "arc" furnace. Henry, at Princeton College, New Jersey, had an electric furnace that was more than a scientific toy. Pepys in 1815 made a few scientific experiments.

Despretz, in 1849, made the original furnace of the "resistance" type. But this was the "scientific" age of electric furnaces, when it was used by the investigator simply as an aid to scientific experimental work.

In 1881 Edison first exhibited the dynamo or electric generator and electric motor. This machinery had the virtue that it worked and was reliable and durable. Such parts and accessories as fuses, switches, porcelain cleats, insulated wire, etc., were developed by the American inventor as essential details of the dynamo in a form identical with the present form though crude.

With the practicalization of the dynamo the inventor of the electric furnace had a source of power that could be relied upon. And thus the practical stage of the electric furnace started. Sir W. Siemens, in 1878, exhibited to the Royal Society at London an electric furnace of the vertical "arc" type in which he melted several pounds of steel and boiled off several pounds of copper. See Fig. 1. This furnace is the prototype of the Heroult steel refining furnace and indeed of any furnace that uses a vertical electrode.

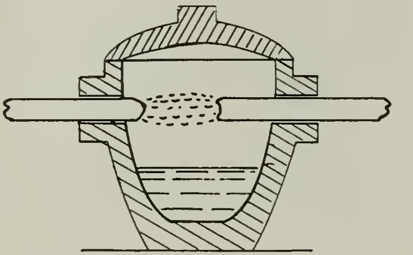

FIG. 2.—HORIZONTAL ARC FURNACE

Siemens also exhibited a horizontal "arc" furnace in which the heat is reflected down to the charge. This is the prototype of the reveberatory arc furnace such as is used by Stassano for refining or melting steel, by the late G. P. de Laval for smelting zinc ores and by Weeks for distilling crude zinc. See Fig. 2.

From the Siemens vertical type of furnace followed the Heroult-Hall electrolytic furnace for the production of aluminium. This was followed by the Wilson Carbide furnace. See Fig. 6. From these two came the slag resistance furnace or the buried arc type in such common use in the manufacture of the ferro-alloys. Siemens therefore can be regarded as the father of the "arc" type of furnace.

In 1883 E. H. and A. H. Cowles took up the question of smelting by electricity the zinc-copper ores of a mine near Santa Fé, New Mexico. Though the Cowles brothers were unsuccessful in this attempt they did develop the "resistance" type of furnace. See Fig. 4. In this a core of conducting carbon as coke in the charge itself carries the current in a horizontal direction. While no direct commercial result, at least no commercial result pronouncedly successful ensued, yet from this furnace was derived more or less indirectly the resistance furnace of Acheson for the making of graphite or carborundum. See Fig. 5.

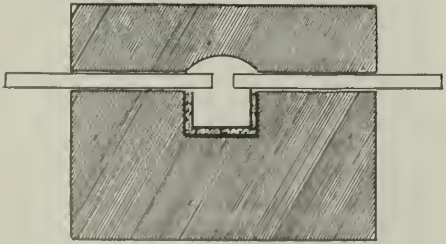

FIG. 3.—MOISSAN FURNACE

Along in 1890 the industrial limits of the electric furnace were clearly seen by certain far-sighted men, and it was recognized that the electric heat could only be used for such purposes as its specific innate advantages gave it a metallurgical monopoly.

This had been evident in the production of aluminium. Here by the combined power of electric heat and electrolytic effect, a metal that sold for $5.00 per pound had been reduced to 50 cents per pound. In calcium carbide, artificial graphite, and in carborundum there was found a useful product which could only be made in the electric furnace.

About the same time, water powers became harnessed and it was fashionable in financial circles to develop hydro-electric installations. This gave a large supply of power for which there was not a great demand except at low rates when sold in large quantities.

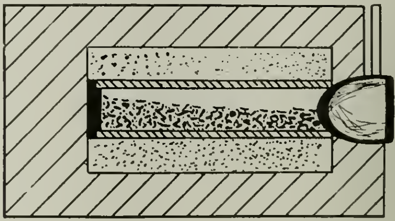

FIG. 4.—COWLES RESISTANCE FURNACE

About 1890 the real "commercial" age of the electric furnace started. The generator was developed to a practical stage, there was an abundance of cheap power and enough research work had been done to give the art the means of applying to industrial purposes the electric energy.

Along in 1890 Henri Moissan, a professor at Sorbonne, Paris, performed his spectacular researches on the electric furnaces. See Fig. 3. With upward of 200 hp at his disposal he concentrated this in less than a cubic foot of laboratory space. As electric furnaces nowadays rarely work at a power density greater than 20 kw per cubic foot, the results attained were remarkable. Almost any oxide was reduced, metals were boiled off in a short time, and the carbides of metals formed.

Unfortunately, such an operation, while it was brilliant from a scientific standpoint, especially the manufacture of diamonds, was not an unmixed blessing to electrometallurgy, for it gave rise to hopes and anticipations from which there was little realization.

When the calcium carbide business began to lag before acetylene found its present large uses, the companies making it turned their energies largely to the manufacture of ferro-alloys. As most of these are difficultly reducible, the electric furnace became the proper metallurgical means to employ. Along in 1905 the production of ferrosilicon high in silicon became an industrial success of importance. Ferro-vanadium, ferro-chrome, ferro-molybdenum and ferro-titanium followed. This expansion was due in part to the increasing demands of the metal business for these alloys which were used as a basis for special steels or as scavengers in the manufacture of steel. This business has in certain cases been markedly successful in producing profits.

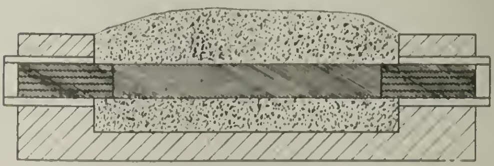

FIG. 5.—ACHESON RESISTANCE FURNACE

About 1905 the production of fine tool steel in the electric furnace came into engineering prominence. Steel when made in the crucible is expensive but its duty is hard, for tool steel must be as nearly perfect as is practically possible to manufacture. The cost of production is large for the crucibles are expensive, the labor charge high, and the thermal efficiency miserably low. In either the Bessemer converter or the open-hearth furnace, it is hard to make steel dense without infinitesimal blow-holes or "sonims." The process of electric refining is more expensive but the quality of the product that can be made compensates for its higher cost. In the electric steel furnace there is a neutral atmosphere and the steel is "dead-killed." The reaction between the sub-oxide of iron and iron carbide is brought to a state of stable chemical equilibrium and the steel is never poured "gassy" while it is not an easy task to always pour steel dead quiet from a Bessemer converter or from an open-hearth furnace.

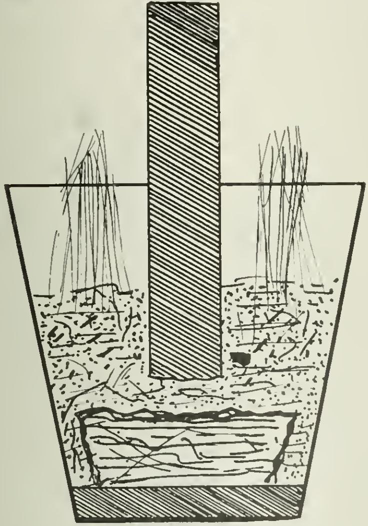

FIG. 6—WILSON CARBIDE FURNACE

It seems an economic mistake for the electric furnace engineer to have tried to refine "tonnage" steel in the electric furnace when the crucible steel business lay open as a much easier point of attack in spite of the conservatism of the crucible steel makers. But the genius of Heroult had developed the combined process of partial refining by fire processes with subsequent electric furnace treatment. With the demand for heavy section rails by the railroads of great hardness and great toughness and with the proven industrial success of electric steel castings such as is done at Schenectady by the General Electric Co., however, the electric steel furnace on which Heroult has spent so much time, money and energy and to which art he has contrbuted so much, has two avenues of commercial expansion. There are few businesses that offer so great a profit with so little risk as does the manufacture of steel castings from cheap preheated scrap in the electric furnace.

The "induction" furnace has been subjected to commercial exploitation. It has had some success abroad but practically none in this country, for it is doubtful if of the 200,000 odd tons of steel made in the electric furnace in the United States one per cent has been made in the electric "induction" furnace.

The manufacture of carborundum came from the chance invention of E. G. Acheson. He noticed a hard substance in some electric furnace experiments. These were harder than glass and would slightly cut the diamond itself. From this came the carborundum furnace in which a mixture of sand and coal dust are turned into a useful abrasive. Mr. Acheson noticed, after his carborundum process had been commercialized, a layer of graphite in what had been the hottest zone of the furnace. This, he reasoned, had been formed by the decomposition of the silicon carbide. Accordingly, he developed the manufacture of artificial graphite by employing iron oxide or other substance to act as a high temperature catalyser to graphitize the carbon.

This process was successfully turned into the manufacture of graphite electrodes which have been in and of great service both in electrolytic and electric furnace work. It is hard to see how many electrolytic processes could be used at all without Acheson graphite anodes. Acheson graphite has the great advantage of standing sudden temperature changes without breaking. Often the increase of service more than pays for double increased cost as compared to carbon electrodes, although in most instances the value ratio to carbon is about 2.5 to 1.

With all these successful developments from 1890 to 1905 (the unsuccessful electric furnaces have perished and are forgotten) we might almost say that we have reached the end of the first "commercial" stage of the electric furnace. The electric furnace proved its usefulness in certain fields of its own. It did not begin to invade the field where the "carbon heated" furnace was clearly established until 1905.

Such developments as the manufacture of calcium nitrate in the electric furnace was along the lines of metallurgical monopolies.

In 1905 the advance of the old and tried processes began. The only two that had been successful before were the manufacture of carbon disulphide by Taylor and of phosphorus by the Oldbury Chemical Co. The electric steel furnace has proved its commercial worth in the manufacture of tool steel. The electric zinc ore smelting furnace and the electric brass furnace are destined to successfully invade the field now held by the zinc retort and the brass crucible.

The electric current is a powerful metallurgical instrument. But a keen sense of its own limitations must be present in the minds of the designer, inventor and promotor. The electric current resembles to the authors' ways of thinking—a hydraulic jack, but a hydraulic jack, while adapted for raising a steel furnace, is not made for raising a packing box.

---

**Paving Brick from Blast-Furnace Slag.**—At Middlesborough, England, several companies are engaged in the manufacture of brick from slag. The latter is taken from the furnaces in a car from which the molten slag is run into moulds carried on a wheel. The brick formed from the congealed slag is subjected to an annealing process before they are ready for use.

**The Iron and Steel Institute** announces the annual award of a research scholarship or scholarships, of such value as may appear expedient to the Council, founded by Mr. Andrew Carnegie, who has presented the Institute with $100,000 for the purpose. The award is to be made without respect to sex or nationality. Candidates must be under thirty-five years of age. The object of the scholarships is to conduct researches in the metallurgy of iron and steel. No restriction is placed on the locality in which research is to be carried on, provided it be properly equipped for the purpose. Appointments are for one, renewable at the discretion of the Council; the results of research are to be communicated to the Institute. Persons interested may secure further information by applying to G. C. Lloyd, secretary, 28 Victoria Street, London.

# Handling the Raw Materials at the Iron Blast Furnace

BY J. E. JOHNSON, JR.

The average output of blast furnaces has increased in little more than a generation from about thirty tons per day to about five hundred tons per day. This great increase has occurred simultaneously with a decrease in the supply of labor relative to the demand, and a great increase in its cost.

These two circumstances have brought about great changes in the methods of handling the raw materials for pig iron manufacture. These materials are so generally ore, coke and limestone, that unless definitely stated, to the contrary, they will be meant when the term raw materials is used. In furnace parlance these are also known under the name of "stock," and the building in which the supply is stored to cover irregularities in daily receipts is known as the "stock house," a term which has survived the existence of any actual house.

The prime condition for successful operation of the furnace is that it must be run continuously. This is a fact that it will be necessary to emphasize many times in subsequent chapters. This term means literally twenty-four hours a day, seven days a week, fifty-two weeks a year, and for several years at a stretch. To enable furnaces to be operated in this way a supply of raw materials must always be on hand, in spite of the interruption to transportation of supplies, and other conditions which make regular daily receipts impossible. The first and obvious one of these conditions is the occurrence of Sunday, when transportation is always partly and generally wholly suspended. This makes it indispensable to have a supply of raw materials large enough as a minimum for two or three days' run, and rising as high as a six months' supply in many cases.

In the old days of small charcoal furnaces these were generally built close alongside of a very steep hill, and had a bridge running from the top of the furnace over to a leveled yard or space on the hill, served by a wagon road with an approach long enough to permit the hill to be surmounted. All raw materials were delivered by team into the stock house built on this level space, and unloaded, at first by shoveling from the wagons, later by wagons with loose bottoms, which could be pulled out, one board at a time. These materials were shoveled by hand into filling barrows, which were then wheeled onto a platform scale set for the correct weight of the given materials. The weight was adjusted by shoveling into or out of the barrows to make the balance correct, and the barrows were then wheeled across the bridge to the top of the furnace and there dumped. Of other equipment besides shovels, barrows and scales there was none. The number of men employed was not very great because the quantity of material handled in a day was small. Fifty years ago it probably did not average much over one hundred tons in twenty-four hours, and as a small number of men could handle this amount of material, equipment would not have been needed had it been available.

With the great increase in the size of the units, conditions became more and more difficult. The gangs of men required to feed a furnace grew to be large. The work was hard and it was very difficult to maintain full gangs. It must be borne in mind that no delays could be tolerated. A short suspension of filling would let the furnace get "down," which would probably be reflected in poor iron or in some other form of bad furnace work the next day.

More than 80 per cent. of the iron produced in the United States is made from ores mined in the Lake Superior region and transported wholly or partly by water to the points of consumption. Navigation on the Great Lakes is open nominally seven months, but actually only about six in each year. Therefore furnaces which derive their ore supply from this region are under the necessity of having on hand a six months' stock of ore at the close of navigation. If the furnaces are some distance removed from the receiving port of the ore, the latter may be stored on the docks or at storage yards maintained by the railroads. But the best practice increasingly tends toward shipping the ore directly to the furnace plant, and storing it in an ore yard devoted to that exclusive purpose, and not infrequently equipped with powerful and expensive machinery for putting the ore into the stock pile and reclaiming it as needed throughout the year.

A plant of four furnaces, of five hundred tons daily capacity, is not a large one as furnace plants go to-day, but such a plant consumes four thousand tons of ore per day, or 1,460,000 tons per year, and all of this must be stored during six months or less and half of it, say 750,000 tons, must be reclaimed from storage during the six months which includes the winter weather, and principally in the severe climate which characterizes the central district of the United States. As it is characteristic of the Lake Superior ores to carry from a minimum of five or six, to a maximum of twenty-two or twenty-three per cent. of moisture, with an average of ten or twelve per cent.; and as this moisture is not combined with the ore, but only held by it in the shape of moisture, these great stock piles freeze to a depth of several feet, and the ore being soft and plastic, like clay or sandy loam in most instances, the frozen mass is exceedingly hard. Machinery well able to handle the material in its unfrozen condition would be unable to stand the service on frozen ore for the briefest period. This adds another very severe condition which must be met in handling the raw materials for iron manufacture in a preponderating portion of the business.

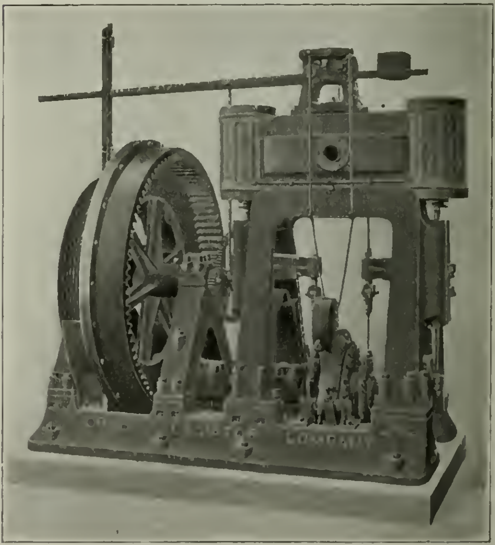

FIG. 1—STEAM-DRIVEN BLAST-FURNACE HOIST FOR FURNACE WITH VERTICAL HOIST TOWER

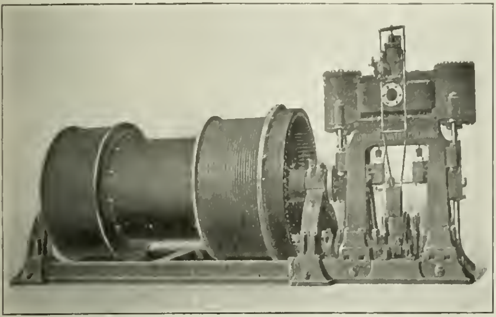
### Power Hoisting

The first change from the primitive arrangement I have described was the introduction of power hoists for taking the material to the top of the furnace. These were of two kinds, vertical and inclined, but irrespective of this in the majority of cases a platform was used onto which the barrows were rolled by men at the bottom. The platform was then hoisted, whether vertically or on an incline was a matter of detail, and men at the top, known as the top fillers, took the barrows off the car, distributed them around the top of the furnace and dumped them.



FIR. 2—STEAM-DRIVEN HOIST FOR A SKIP-FILLED FURNACE

The introduction of power hoisting as a substitute for the bridge method of bringing the material to the top of the furnace was necessitated by the increase in the height of the furnace from some twenty-five or thirty feet to fifty, sixty and seventy feet. No hill could be found steep enough and high enough to lend itself to filling purposes for furnaces of such heights.

The operation of filling being continuous, and the need for capacity growing rapidly after the introduction of power hoisting, double acting hoists were introduced very early and are used almost universally, with certain exceptions to be noted later. By this means the platforms, cars and filling barrows balanced each other on the ascending and descending trips, leaving only the useful load of the charge to be hoisted. This effects the saving of a great deal of power, and permits the use of much smaller hoisting apparatus.

Many styles of hoisting apparatus were tried in the early days of power hoisting, hydraulic, pneumatic, water balance and various types of engine driven hoists were used. Nevertheless this was one of the earliest parts of the equipment to become standardized, and for many years there has been used a very simple type of vertical two-cylinder engine, with cranks at right angles, and the engine shaft geared to the rope drum with either a single or double reduction gear. These engines are not fitted with a link like that used for reversing locomotives and other high grade engines, but are reversed by running the steam in opposite directions through their ports. One set of openings constitutes the inlet when running in one direction and the exhaust in the other.

In order to operate successfully on this system the valves must be set without "lap" or "lead," the eccentrics being exactly at right angles to the cranks, so that the steam follows the piston full stroke, and is not used expansively, even to the slightest degree. As a result these engines are very extravagant of steam, using about one hundred and twenty pounds per horsepower per hour as against twelve to twenty pounds for ordinarily good engines in power stations.

In the last ten or fifteen years there has been a growing tendency to avoid this great waste of steam by the use of motor driven hoists, these obtaining their current from generators in the power station, driven by an engine using not much more than a tenth of the steam per horsepower that is required for the hoisting engine.

There are, however, problems of control which have had to be met and which have proven rather difficult. With the large masses of material now handled it is very important that the operation of hoisting be started and stopped gradually to eliminate the excessive stresses which would otherwise arise. These problems have been solved successfully with the steam hoisting engine by the use of supplementary throttles thrown in and out of operation by a cam traveling at a suitable reduced speed. In order to accomplish the same result with the electric hoist, sliding contacts and a great multiplicity of switches were at first considered necessary, so that the switchboard for such an apparatus was very large, elaborate and expensive.

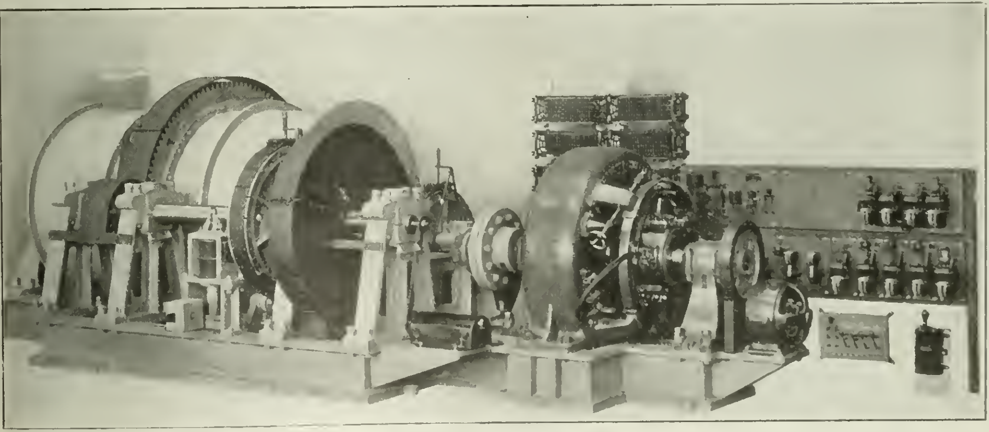


FIG. 3—ELECTRIC HOISTING APPARATUS

This problem has, however, been worked out successfully, and such electric hoists are now articles of regular manufacture, as are the steam hoisting engines previously mentioned. Fig. 1 shows a modern steam-driven blast furnace hoist for a furnace with a vertical hoist tower, where the ropes are led by guide sheaves from the tops of their respective cages to points vertically over the opposite sides of the drum, so that when the rope from one cage is winding up that from the other is unwinding. The cages are thus balanced through the hoisting drum rather than directly. This hoist is built by the Otis Elevator Company.

Fig. 2 shows a steam-driven hoist for a skip filled furnace, in which there are two distinct drums, separated by a suitable distance horizontally so that the center of each drum shall be in the central plane of its skipway. This will be more fully explained in dealing with skip hoists. This hoist is also built by the Otis Elevator Company.

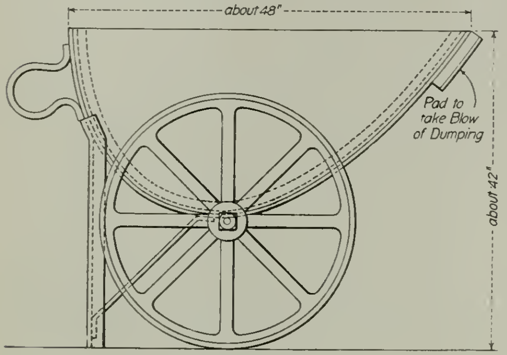

FIG. 4—ORE BARROW

Fig. 3 shows an electrical hoisting apparatus with its switchboard, built by the Lidgerwood Manufacturing Company. It will be seen that the rope drums in this are the same type as that shown in Fig. 2, this also being for a skip filled furnace.

### Hand Filling and Filling Barrows

The system of handling raw materials in barrows was almost universal until the middle of the decade beginning in 1891. Many attempts had been made to eliminate at least a portion of the labor required for handling the great quantity of material needed as furnace outputs increased. But these were either mechanically unsatisfactory, or else their effect upon the work of the furnace was detrimental, in many cases disastrous. The reasons for this, in so far as they are known, will be given at some length in the chapter on operation; suffice it for our present purpose to say that probably ninety-five per cent. of all the iron made for thirty or forty years previous to the time mentioned was made from raw materials handled in filling barrows. These are so widely known that it seems almost unnecessary to describe them, but for logical completeness a brief description may not be amiss.

These barrows are universally two-wheeled, with at least one of the wheels loose on its axle to enable them to turn corners easily, and provided with stout legs on the rear end, which hold them level when standing. They are dumped by tipping forward on the axle, the wheels remaining stationary when they come against the dumping ring on the top of the furnace. On account of the vast difference in the specific gravity of coke, and ore, or limestone, a different type of barrow is generally used for handling these two kinds of materials. The ore and limestone barrows are as shown in Fig. 4, and the coke barrow as shown in Fig. 5. The latter are much larger and provided with a door in front, which is held shut by a latch, this latch being released from the rear a moment before the barrow is dumped. This construction is used in order to obtain a reasonable capacity for so light a material as coke. These barrows are built of steel plate, very substantially riveted together throughout, as they are subjected to continuous service and particularly to very heavy shocks when they are dumped, the nose of the barrow dropping forward on the iron dumping ring with a hard blow.

In ordinary practice the barrow weighs about eight hundred pounds, and will carry a load of about fifteen hundred pounds of ore. Ordinarily they are not loaded quite as heavily as this, as they then become too difficult for one man to handle, even on good floors.

The capacity of the coke barrow is roughly one-half as much by weight, so that the same number of barrows of coke as of ore are required per charge, the ore charge weighing normally about twice as much as the coke charge.

The physical labor involved in wheeling the barrows from the stock piles to the foot of the hoist is in ordinary practice roughly the same as filling them by hand. Therefore to dispense with hand shoveling, and continue the use of filling barrows, is only a half solution of the problem of eliminating manual labor in filling. Moreover, when the barrow system of filling is used it is necessary to have always one, and frequently two or even more men on top of the furnace to take the barrows from the cages to the furnace top, dump them and return them.

This labor is more expensive, man for man, than the labor at the bottom of the furnace, because it does not pay to have a foreman supervise the relatively small number of men required, and yet the operation of dumping, with which they are entrusted, is of the utmost importance, and slight variations in the method of dumping with hand filling, more frequently than any other cause, derange the work of the furnace.

For this reason it is necessary to secure a higher grade of labor for at least one of these top fillers by paying higher wages. Another reason for paying higher wages is that the men are under a certain liability to be overcome by the furnace gas when remaining for a long time on top. It is impossible to make the bell absolutely tight and keep it so all the while. Small particles of stock lodge on its seat and hold it open by an almost microscopic amount until the next dumping, when they are swept off, but very likely replaced by similar particles in some other location, so that the bell seldom shuts absolutely tight.

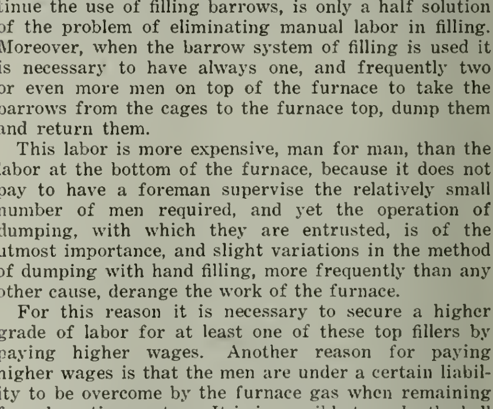

FIG. 5—COKE BARROW

There are other points at which gas can escape, such as the test rod hole and various other places through which the gas will find its way in quantities frequently too small to be visible, but nevertheless tainting the atmosphere sufficiently to overcome men exposed for a long time to this poison, even in this dilute state.

This possibility of accident, though real, is small, and fatalities due to the ordinary course of filling almost unknown, nevertheless it is sufficient to necessitate a higher scale of wages.

For all these reasons the elimination of manual handling of the stock from the bins to the furnace top was the goal of furnace builders for many years. But as the manager of the furnace was rarely the engineer who built it, he looked at the matter from a different point of view, and the many failures recorded to the credit of mechanical filling made managers very chary of risking their success and reputation in operating such plants.

### The Duquesne Revolution

In the middle of the decade beginning 1891, furnace outputs had become as high as 400 tons per day in regular operation. The crews necessary to fill them by hand labor using these barrows were tremendous. Then, too, the capacity of the platform hoists had almost reached their limit, and it became almost a matter of physical impossibility to fill furnaces for any greater output by this means. Accordingly when about 1895 the Carnegie Steel Company decided to build at Duquesne a plant of four furnaces with a capacity of six hundred tons per day each, these furnaces being about twenty-one feet in diameter by one hundred feet high, they determined to strike out on new lines and eliminate altogether hand labor for filling.

M. A. Nieland was then chief engineer of the Duquesne works, and he designed what has since become one of the standard methods of mechanical filling, commonly known as the bucket system. This was a success mechanically and metallurgically and was the beginning of a revolution in the construction and operation of blast furnaces. It having been demonstrated that mechanical methods could be made to operate successfully on so large a scale, and with an enormous saving of labor, other methods to achieve these ends were soon devised, and as a result it is probably safe to say that three-fourths of all the iron now produced is made at furnaces mechanically charged.

The plan of eliminating labor wherever possible was carried out in all directions at this plant, whose mechanical equipment throughout was the best obtainable at that time. Thus the construction of this plant marks a distinct epoch in the history of the blast furnace in the United States.

### The Delivery of the Stock to the Furnace

Returning now to the matter of handling raw materials from the stock piles to the barrows, this, as has already been stated, was at first done exclusively with shovels, but when the introduction of railroad transportation replaced the delivery of the raw materials to the plant by team, it was soon found necessary to elevate the tracks on trestles to facilitate unloading the material from the cars.

The cars were at first of the flat-bottom type, but very soon hopper-bottom cars, the prototypes of those in use to-day, were introduced. For these trestles became absolutely necessary. It was then a short step to install bins underneath these trestles, into which the materials could be dumped directly from the cars, and from which, in turn, they could be drawn directly into filling barrows without hand shoveling.

This eliminated probably fifty per cent. of the labor of filling, and, considering the great returns which the investment in bins pays in the form of labor saved, it is surprising that their introduction was not more rapid, but at the time of the Duquesne revolution many plants which considered themselves modern and well equipped were still handling their raw materials largely or wholly by hand. Since that time, however, the use of bins in large plants has become practically universal.

It will be seen that the order in which we have followed these developments, in the hoisting of the material, in its transportation from the stock house to the furnace, and in its delivery into the means of conveyance in the stock house, is the reverse of their logical order. But this is the way the development actually occurred chronologically, and to consider them in this order is perhaps justified on this account.

In discussing the development of mechanical filling, it is now necessary to revert to the subject of the delivery of the ore, for so large a part of the ore in this country is transported by water, and only during a relatively brief season, that this has had profound influence, not only on the handling of the ore at the ports of receipt, but also at the blast furnaces, because the machinery which was developed for unloading the boats was found almost equally valuable, with slight modifications, at the blast furnace also.

The conditions of water transportation imposed two difficulties on this traffic. First, the difficulty of unloading ore from the holds of vessels well below the water line, lifting it to a sufficient elevation and transporting it to a sufficient distance to enable it to be deposited in a stock pile, and, second, the necessity of doing this in the least possible time.

As has so often happened in industrial history, the solution of these difficulties resulted in an eventual benefit of enormous importance to the industry concerned. Less than a generation ago, boats of two or three thousand tons, the largest then in service on the Great Lakes, could be unloaded only by shoveling the ore by hand into tubs, hoisting these with ropes, dumping them on the wharf and then wheeling the ore up an incline onto the stock pile. This took vast quantities of labor, and as the men required physical stamina and endurance to stand up under this work there was a limited market from which this labor could be drawn. As a consequence the supply was always below the demand. This resulted, as it always does in such cases, in making the men arrogant, unreasonable and difficult to manage to a very high degree. This, in conjunction with the high wages it was necessary to pay them, made the unloading process very tedious and expensive.

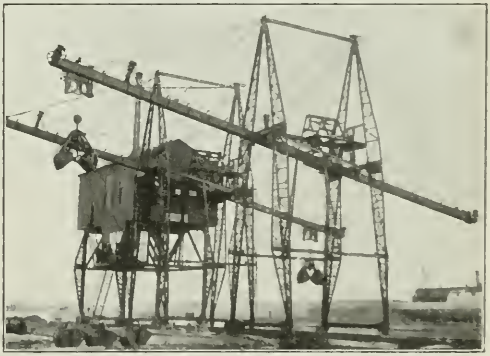

FIG. 6—BROWN HOIST FAST PLANT

During the decade beginning 1881, Alexander E. Brown began to apply his brilliant engineering ability to the problem of performing this work mechanically. His efforts met with the highest success, and other engineers, following in the path which he had blazed, developed still further the possibilities of mechanism in such work. So that while in 1885 it took about three days to unload a vessel of three thousand tons, and cost about twenty-five cents per ton, it is now possible to unload vessels with machinery designed for this purpose in a shorter time than their cargo can be spouted into them from bins on the docks at the Upper Lake ports, and at a total cost for labor, power, maintenance, interest and amortization on investment of not over four cents per ton.

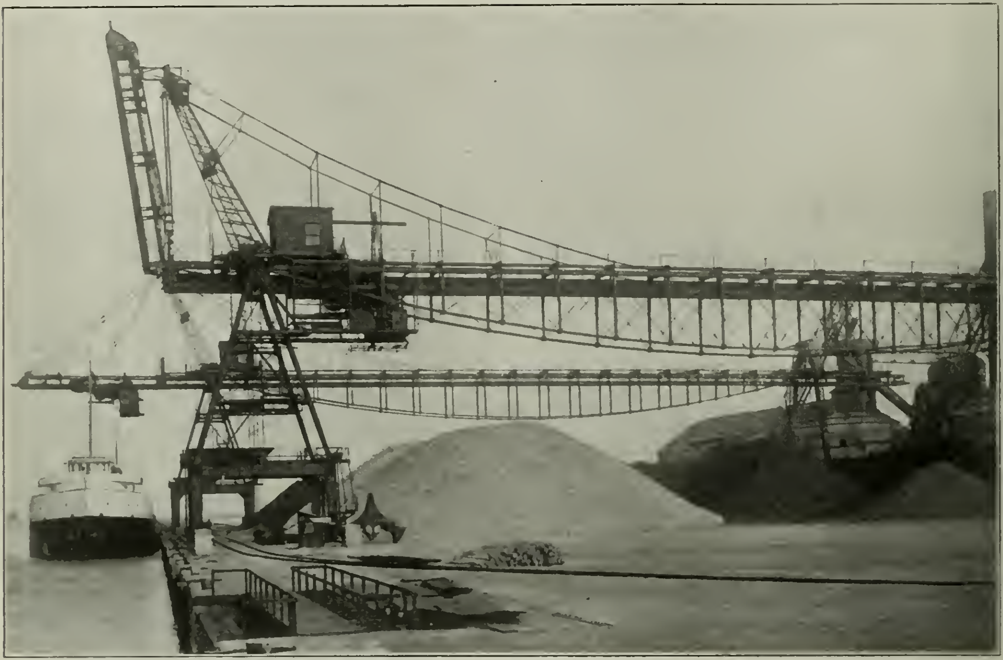

FIG. 7—BROWN HOIST TRAVELING BRIDGE

In the summer of 1912 a steamer containing something over thirteen thousand tons docked at 1:15 and was unloaded and had cleared for the Upper Lakes at 4:35 on the same afternoon. Three hours and twenty minutes to remove thirteen thousand tons of material. Probably not over twenty-five men were employed on the task all told, so that the labor cost was almost negligible. This was a record at that time, though it may have been beaten since.

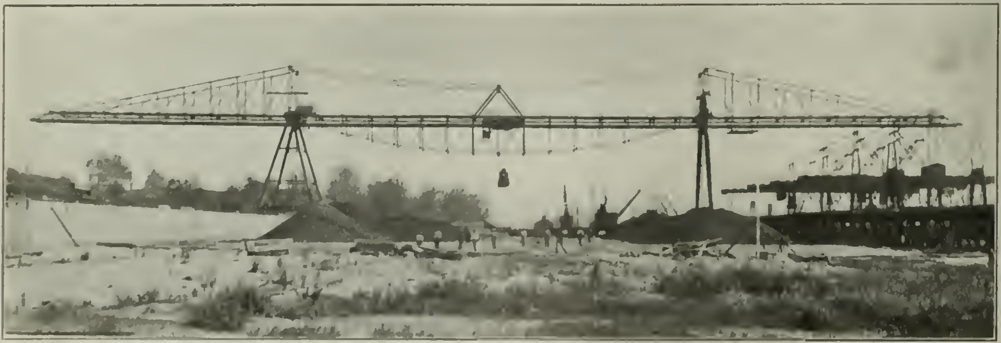

FIG. 8—BROWN HOIST BRIDGE WITH FAST PLANTS IN BACKGROUND ON THE RIGHT

### Ore Handling Machinery

On account of the vast influence of the machinery developed for unloading vessels on the problem of stocking and reclaiming ore at the blast furnace, it will not be amiss to illustrate here some of the equipment by which these results are achieved. Fig. 6 shows a fast plant, designed and built by the Brown Hoisting Machinery Co., and may be considered the legitimate development of the first mechanical equipment built for this purpose by the same company twenty-odd years ago.

Where greater stocking capacity is required than the fast plant trolley travel will cover, traveling bridges are used, as shown in Fig. 7. In these the trolley travels on a straight member of the bridge, which is carried on the two traveling trestles shown. One of these runs on a double set of rails near the dock front, spanning one or more standard gauge tracks, the other on a single rail at the rear end. The bridge is pivoted to the trestles or legs so that it can be slewed at a considerable angle. The runway is carried beyond the line of the traveling legs on cantilevers, the outer one of which is hinged so that it can be raised up out of the way to permit the bridge to pass the spars of vessels. Equipment of this type is used particularly where the furnace plant is at the lake front. Where the stocking capacity required is so great as to necessitate the employment of bridges and where rapid unloading capacity for the vessels is also required a combination is made of the two styles of equipment. Several fast plants remove the ore from the vessels and dump it within reach of the bridge, which picks it up again and stocks it as required, as shown in Fig. 8. This system will be described more in detail in conjunction with the Hoover & Mason and the Wellman-Seaver-Morgan apparatus.

Fig. 9 shows in diagrammatic style a Hoover & Mason unloading and stocking apparatus. This consists of two distinct parts. First, a gantry crane with cantilever extensions, one side of it is carried on wheels running on the top of the left hand wall of the ore trough, the other on wheels running outside the railroad tracks close to the dock face. This gantry supports a horizontal runway for a trolley from which hangs a grab bucket, shown in its open position after descending into the ship's hold, at the extreme left.

The method of suspension of this grab bucket is such that it may be rotated at any angle, for the reason that it can only go through the hatches when turned with its long axis parallel with the hatch. But in order to reach out beyond the hatch line and get the ore between the hatches, it is necessary for it to be able to rotate so that its long axis is at right angles to the line of the hatch.

The operation of unloading is carried on as follows:

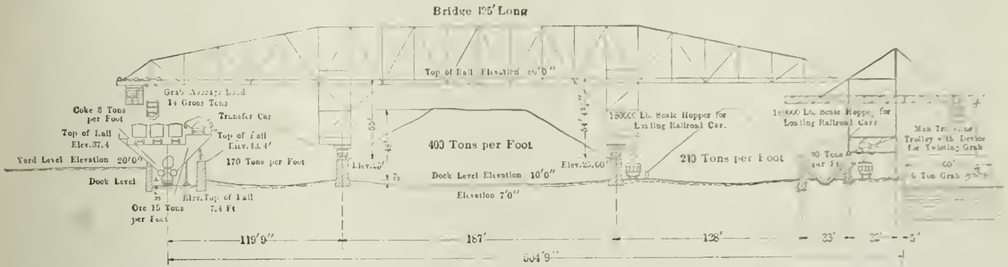

FIG. 9—HOOVER AND MASON UNLOADING AND STOCKING APPARATUS

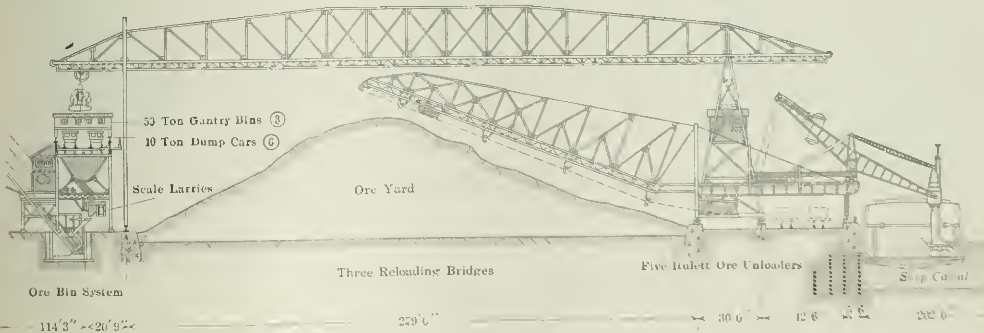

FIG. 10—HEWLETT UNLOADER IN CONNECTION WITH ORE BRIDGE

The grab bucket is lowered into the ore, closed, turned parallel with the hatch and elevated to a position alongside the cab hanging from the trolley. The whole trolley is then traversed back to one of two positions and there dumped. The first position is just to the left of the center of the gantry; the other on the left-hand extension of the cantilever outside the gantry. In the first position it discharges into a small hopper and from there the ore is loaded into railroad cars for direct shipment. In the second case it discharges into a concrete trough, from which the ore is reloaded by the second portion of the apparatus.

This consists of a traveling bridge one hundred and seven feet from center to center of supporting legs, with cantilever extensions on each end, running its total length up to four hundred and ninety-five feet. This bridge is also equipped with a trolley and grab bucket, the latter being of more than twice the capacity of the one which goes into the ship's hold, which is of six tons' capacity, the one on the main bridge being of fourteen tons.

This bridge travels on tracks laid on concrete walls, raised up well above the level of the ore yard, so that the ore will not run down on the tracks even when the yard is filled about to its capacity. The trolley and grab bucket on the main bridge use the ore in the trough as a source of supply, and taking it out of this trough carry it back to any one of the three piles under the three portions of the bridge and there dump it.

The drawing is so plain as not to need very much detailed explanation. Means are provided whereby ore may be shipped out by rail from two or three points. At the lefthand end of the drawing is the bin system for the furnace itself, this plan having been prepared for a furnace plant located just back of the dock line on the lake front, but a plant of the same general type would be used if the ore were merely stored in the yard and shipped out as required through the winter.

It will be seen that the gantry unloaders are relatively inexpensive as compared to the main ore bridge, and it is therefore commonly possible to have five or six of these all working on a vessel at the same time, and delivering their ore into the concrete trough. The large bridge follows these and keeps the trough sufficiently clean for them so that they are free to dump in it when they move, as required by the contents of the hatchways, etc., thus the unloaders can be devoted to the purpose of unloading without much consideration of the question of ultimate disposal.

The bridge, on the other hand, is an extremely expensive apparatus, and, being many times heavier than the gantries, cannot be moved back and forth as they are, though it can move with sufficient ease to follow them at intervals and keep the ore trough free for them. By this combination rapidity of unloading is secured without excessive expense for long-span bridges.

The latest developed apparatus for unloading is that brought out by the Wellman-Seaver-Morgan Company, and named for its inventor, Mr. George H. Hewlett, the Hewlett unloader. A diagram showing this in conjunction with an ore bridge is shown in Fig. 10. This apparatus is equipped with a grab bucket, a modification of the old clam shell bucket, but with two important differences from the machines of Brown and Hoover & Mason. First, the bucket, instead of being suspended by ropes, is carried at the lower end of a rigid column.

Second, the grab bucket, instead of having both jaws symmetrical, as is the case with the suspended buckets, has one jaw provided with a horizontal traversing motion, so that after it is opened, with the jaw swung up into the vertical position, it can be extended several feet horizontally, and by being lowered into the ore in this position serves to pull the ore toward the center of the bucket with a motion exactly like that of a gigantic hoe.

The operator rides in a small chamber in the stiff leg which carries the grab bucket. This is raised and lowered by a walking beam supported on trunnions, which are carried on a truck provided with means for traversing itself back and forth in the plane of the walking beam, that is in a plane at right angles to the dock line. The track on which the truck or trolley moves is carried by a traveling gantry bridge running on a pair of tracks, one close to the face of the dock, the other some distance inshore, as shown. The column, or stiff leg, which carries the grab bucket, is held in a vertical position irrespective of the angle of the walking beam by a parallel motion.

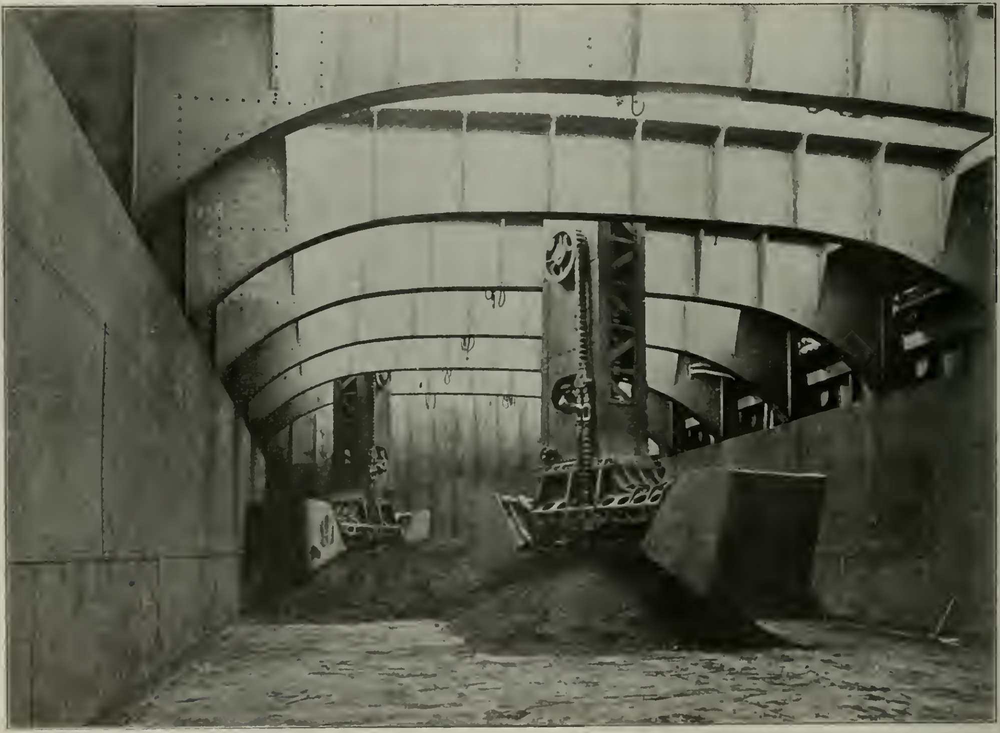

FIG. 11—HOLD OF VESSEL WITH THE GRABS OF TWO HEWLETT UNLOADERS AT WORK CLEANING UP THE FLOOR

The grab bucket and part of its load are counterweighted at the opposite end of the walking beam to reduce as much as possible the amount of power required for raising it and to facilitate its control.

In operation the walking beam is tipped to lower the grab bucket through the hatch, the stiff leg is then rotated to throw the longer arm of the grab bucket into any desired position, and if only a small quantity of ore remains in the hold at this location, the long arm of the grab is then used to pull several piles of ore together so as to make an approximately complete load for the grab, which it then picks up, so that it always goes up from the hatch loaded to its capacity. This capacity is very large. For a time ten tons was considered to be the limit, but several machines are now in successful operation with fifteen-ton grabs.

After the grab bucket is raised out of the hold the truck which carries the walking beam is traversed inland until the grab comes over to one of two or three alternative points of discharge. Two of these deliver directly to railroad cars on tracks running between the legs of the Hewlett. The other is a small retaining hopper running on wheels which travels on the landward cantilever extension of the machine.

In case stock piling is to be done the grab bucket discharges into this traveling hopper, which then runs out on the cantilever and discharges on the stock pile. If more stock pile room is desired than can be reached by the cantilever, then a traveling bridge is brought into play precisely as described for the Hoover & Mason apparatus. The photograph (Fig. 11) on the preceding page shows the hold of a vessel with the grabs of two of these unloaders at work cleaning up its floor. No hand work has been done in this hold, yet it will be seen that the floor is almost as clean as if it had been swept, except for the piles on which the buckets are still operating.

Fig. 12 shows one of these Hewletts complete, though not provided with a long cantilever extension, but with a bridge in the background to do the stock piling.

Fig. 13 shows three Hewletts working on a vessel with the piles of ore at their landward ends, and the outer end of the bridge, which is making the stock pile, in foreground. Fig. 14 shows four Hewletts working on a steamer with stocking bridge behind them.

The absolute control of the mechanism which the operator exercises by having it rigidly supported instead of swung, and by the fact that he himself is immediately upon the bucket and can see to control its movements accurately, gives this machine advantages in handling bulk cargoes not enjoyed by any other type of machine. One of these advantages is that this accurate control of the grab bucket enables the operator to avoid striking the bottom of the hold severe blows

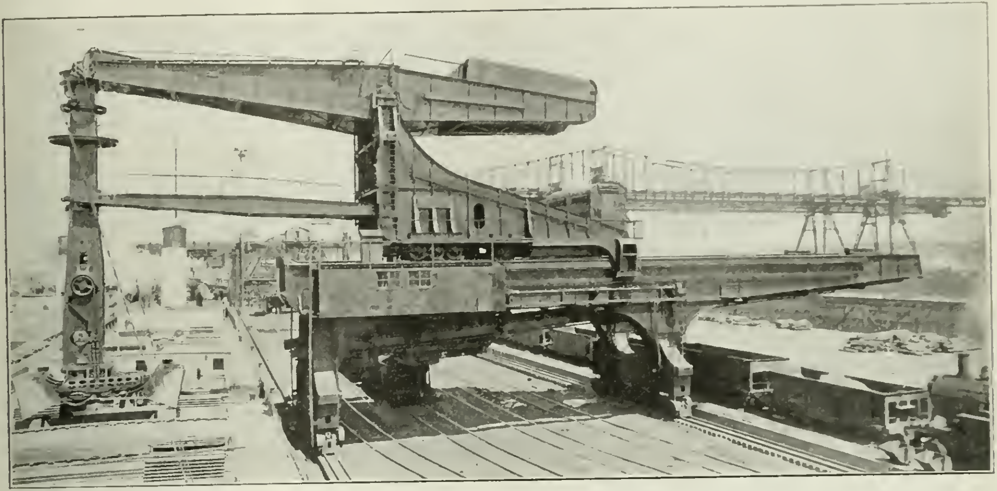

FIG. 12—HEWLETT COMPLETE

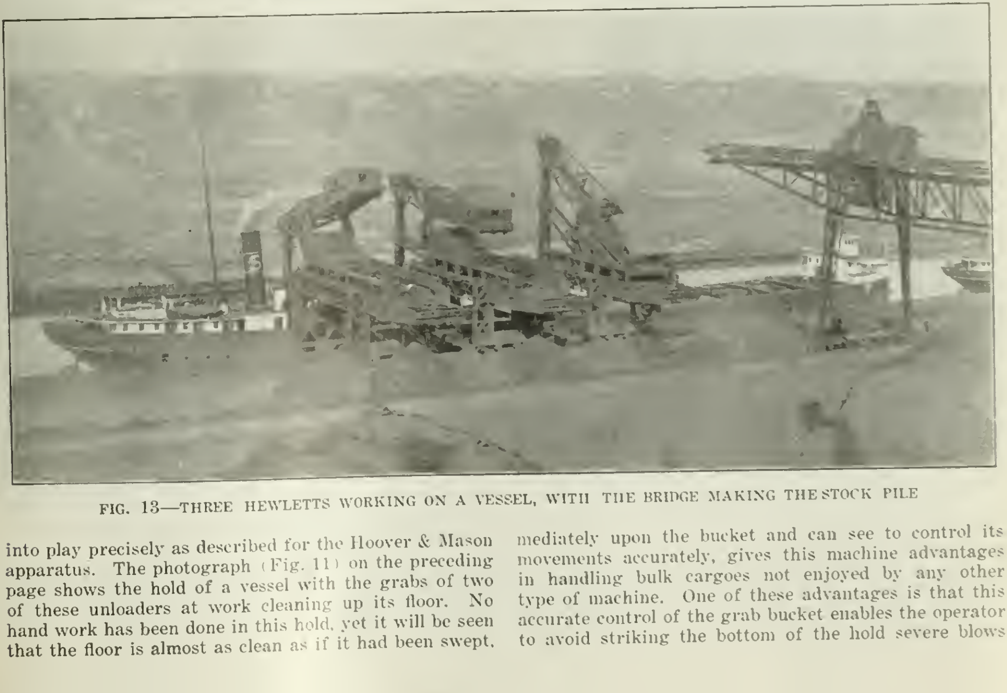

FIG. 13—THREE HEWLETTS WORKING ON A VESSEL, WITH THE BRIDGE MAKING THE STOCK PILE

with the bucket, as frequently happens with older types of apparatus.

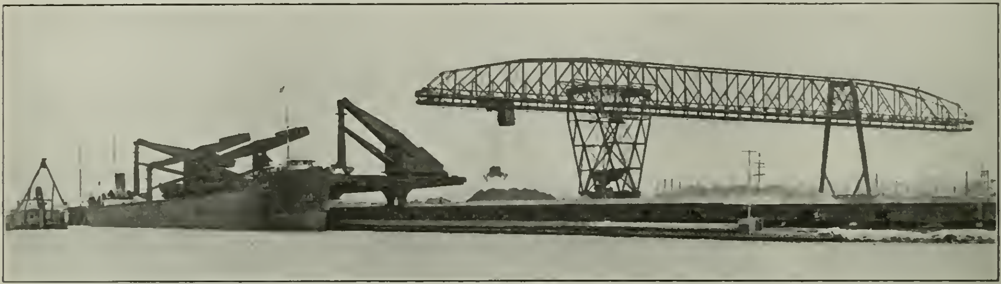

FIG. 14—FOUR HEWLETTS WORKING ON A STEAMER WITH THE STOCKING BRIDGE BEHIND THEM

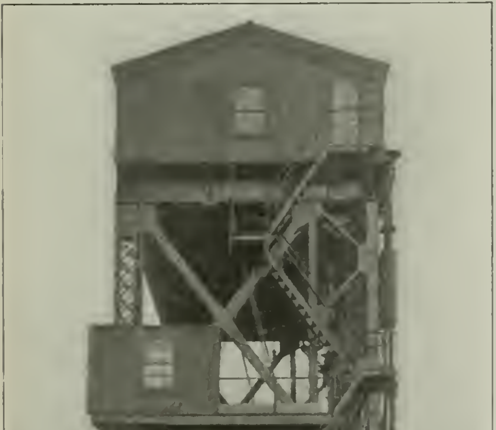

FIG. 15—CAR DUMPER

In reclaiming the ore from the stock pile for use at the furnace the operation is very similar to that of stock piling. But in this case also it is necessary to provide some more easily movable means than the bridge itself for carrying the ore from the bridge to the point of consumption. It will be readily understood that there are always several, and maybe very many varieties of ore in the stock pile, and on account of the great difficulty in keeping these separated, the same kinds of ore are always piled together, so as to make the individual piles as few in number and as large as possible.

When any given kind of ore is desired for the furnace therefore, the ore bridge is moved over this pile and the grab bucket set to work on it. At the furnace or discharging end of the bridge it spans at least one and generally several tracks. Each traverses the tops of the bins from which the immediate supplies of raw materials are drawn. On one or more of these tracks runs a drop bottom transfer car, generally driven by an electric motor under the control of its operator. Such a car can carry fifty or more tons of material at a trip. The distance from the bridge to the bins where the ore is needed being only a few hundred feet, it can readily run back and forth from bridge to bins, and serve the bridge about as fast as the latter can reclaim the ore.

Many variations of this general plan of operation have been worked out. In some places removed from the Lakes the ore is received in drop-bottom cars, which are dumped from trestles, and the ore then reloaded as needed, either by taking the furnace-filling equipment direct to the stock pile and there loading it by hand, or by reloading the ore with clam-shell buckets, operated by locomotive traveling cranes, loading it into cars on the trestles, taking these to the bins and dumping

### Car Dumpers

Plants removed from the lake shore must, of course, receive their ore by rail, and the enormous quantity to be handled in the relatively brief open season has made desirable in some cases a greater speed in dumping than can be secured even with the modern drop-bottom type of ore car.

To meet this condition an apparatus called a car dumper has been applied at some plants. This apparatus has been built in two styles, stationary and moveable. The moveable type is greatly to be preferred, because when a stationary dumper is used some style of transfer car is needed to carry the ore from the car dumper to the stocking bridge, which must stand in the location at which it is desired to stock the ore. With the traveling type of car dumper this is not necessary. The car dumper is moved along on its own tracks, just in front of those carrying the rear end of the bridge, and the car when dumped delivers the ore to the exact spot where it is most easy for the bridge to pick it up.

The general appearance of the car dumper, just back of the retaining wall of the ore yard, with a car standing in it, is well shown by the photograph, Fig. 15.

This apparatus can easily dump one hundred and fifty cars per day of ten hours, and most of the cars used in this service carry about fifty-five gross tons. It will be seen that the amount of material which can be handled through it in a given time is enormous.

In spite of the enormous capacity and great efficiency of these machines for the purpose intended, it may be doubted whether very many plants require the dumping of so vast a quantity of ore in a given time as to compensate for the heavy interest charges on the investment involved in one of these machines, especially in those cases where the ore yard is provided with elevated tracks from which dumping may readily be done.

In such a case the amount of labor involved in dumping the desired number of cars of ore from modern drop-bottom cars is not great, and its cost in all probability does not offset the interest and amortization charges on a car dumper.

At those plants in which the location of the ore yard is relatively high, and it is impractical to provide an elevated dumping trestle, the car dumper undoubtedly furnishes the best solution of the problem when considerable tonnages are to be handled.

### Power Used

Various kinds of power have been used from time to time for operating the various types of ore-handling machinery, described and illustrated above, but it is safe to say that at the present time no power is seriously considered for this service under any ordinary conditions except electricity. This is supplied either from trolley wires or from sliding contacts, like a third rail, parallel to the track, as the circumstances may require.

Whether alternating or direct current is to be used is a matter of some discussion among experts in this field, but in the majority of cases direct current at 220 volts is used, because of the superiority of control which the direct possesses over the alternating, and because with this kind of current dynamic breaking can be used in addition to mechanical brakes for retardation of the moving parts. This can not so easily be done with alternating current.

Each plant presents ore-handling problems of its own, and in each case the problem must be worked out on the basis of the conditions to be met. Enough has been said to give a substantial idea of the general outline of the operation.

*(To be concluded)*

## Synopsis of Recent Chemical and Metallurgical Literature.

### Iron and Steel

**Pulverized Fuel for Metallurgical Furnaces.**—Supplementing an abstract on this subject in our last issue, we give a synopsis of a paper by Mr. JAMES LORD, published in the October, 1913, number of the *Proceedings* of the Engineers' Society of Western Pennsylvania. Mr. Lord gives the experience of the American Iron & Steel Manufacturing Company, Lebanon, Pa., of which he is president. This company has been using pulverized fuel at its plant, in experimental and practical ways, for the past ten years. "From the first it was apparent that its economical use depended upon the absolute control of the feed by the burner. This having been accomplished, we have applied it to over 100 furnaces of various types, such as those for puddling and heating, and of smaller sizes for re-heating nut, bolt and spike bars. It has proved to be a commercial success for all the above purposes, and the experience of ourselves, and others working along similar lines, shows that it can be used with equal economy for basic open-hearth steel furnaces, either with or without checker work. Our experience in the use of this fuel over a number of years has been so satisfactory and so economical that we are now largely increasing our installation, and are about to apply it to open-hearth steel furnaces."

Mr. Lord gives the following requirements for success with pulverized fuel: Both free and combined moisture in the coal must be less than 0.5 per cent; it must be pulverized fine enough to permit 95 per cent to pass a 100-mesh screen, and over 80 per cent to pass a 200-mesh screen; the delivery to the furnace must be controlled by the burner; the coal should have a high percentage of volatile combustible matter, not less than 30 per cent; the sulphur should not exceed 1 per cent.

The following figures show the pounds of fuel necessary to produce 1 ton of puddled bar, made from gray forge pig iron:

| Furnace No. | April | May |
|---|---|---|
| 23 | 1362 | 1318 |
| 24 | 1164 | 1277 |
| 25 | 1271 | 1472 |
| 26 | 1371 | 1362 |

The average for the same months on a lower grade of pig and cast scrap was 1239 lb.

The cost of preparing pulverized fuel during 1912 was as follows:

| | Cents per gross ton coal produced |
|---|---|
| Fuel | 0.034 |
| Repairs to buildings | 0.002 |
| Operating | 0.145 |
| Power (steam and electric) | 0.221 |
| Repairs, machinery and equipment | 0.200 |
| Total | 0.602 |

Analyzing the last item we find repairs which should be charged over a period of eight years, so that the total cost did not properly exceed 50 cents per ton of pulverized coal produced during 1912. If transmission is omitted, the cost of preparation would not exceed 40 cents.

In heating iron piles for rolling, the following quantities (pounds) of coal were used to produce a gross ton of rolled bars. On steel billets the amount would be one-third less:

| Mill | April | May |
|---|---|---|
| 12-in. Central | 516 | 528 |
| 12-in. West | 544 | 570 |
| 16-in. Central | 519 | 523 |

The paper of Mr. Lord was widely discussed by many members of the society, who gave their experiences with pulverized fuel at different places.

### Gold and Silver

**Treatment of Gold-Bearing Scheelite in New Zealand.**—The scheelite deposits of New Zealand are important sources of tungsten. One of the mines, the Golden Point, has been operated for twenty-five years, and is the principal producer. The ore contains gold as well as tungsten, and its treatment is interesting, as outlined by Mr. CYRIL W. GUDGEON in the *Australian Mining Standard* of Nov. 13, 1913.

The ore is sorted in the mine into first and second grades. On reaching the mill, the first grade is again hand-sorted, yielding from 1 to 2 tons per month of a product containing from 60 to 65 per cent $WO_3$, which is marketed. The reject from the hand-sorting is crushed and jigged, producing a concentrate of 60 per cent $WO_3$ and a tailing which is added to low-grade ore. The low-grade portion is crushed in stamps through 30-mesh screens, and run over amalgamated plates to recover some gold. The value of the ore usually averages $3.60 in gold, and of this $1.55 is caught on the plates. After amalgamation the pulp is classified and concentrated on Wilfley tables. The products are (1) a low-grade tungsten concentrate containing 30 per cent $WO_3$ and 60 per cent $FeS_2$; (2) slime tailing which is discharged, and (3) sand tailing which is leached with cyanide solution. The recovery in the cyanide plant is $1.30 per ton of ore. The low-grade tungsten concentrate amounts to only $\frac{1}{2}$ to 1 per cent of the ore milled, and contains about $2\frac{1}{2}$ oz. gold per ton. This material is then dried and roasted and subjected to magnetic separation for the removal of pyrite. The tungsten product runs 60 per cent $WO_3$; the pyrite contains from 5 to 6 oz. gold per ton. The costs of milling 1998 tons of ore, in cents per ton, were: Breaking and jigging, 3.8; stamping, 55.8; concentrating, 8.0; general, 7.6; cyaniding, 26.6; magnetic separation, 36.0; total, $1.378.

### Analysis and Assaying

**Lead Determination at Broken Hill.**—The *Proceedings* of the Australasian Institute of Mining Engineers, No. 10, 1913, contains an interesting report of the assay sub-committee on an investigation of methods used for analyzing and assaying Broken Hill ores and concentrates. The committee's investigations covered methods of estimating lead, zinc and silver. The samples were prepared by drying at a temperature not exceeding 200 deg. C., and then grinding to pass a 100-mesh screen. The sample thus obtained was rolled on a cloth and finally brought into a cone and flattened. Portions for assay were dipped from the mass with a spatula.

*Lead.*—The methods considered were (1) the molybdate, with two modifications, (*a*) filtering the lead sulphate hot and (*b*) filtering it cold; (2) the chromate, and (3) the gravimetric, weighing as lead sulphate. The general principles of these methods are all well known. Two methods of standardizing were tested, using metallic lead and lead sulphate. For the case of hot filtration in the molybdate method, lead sulphate cannot be used for standardizing, as similar conditions would not obtain in treatment of ore and standard. The accompanying table shows the results of tests made by different assayers (A, B, C and D), with all methods and modifications, determining lead in various ores and concentrates.

*Table A*

| Ores | Ammonium-Molybdate Method. Filtering Cold | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Pb Foil Standard | | | | $PbSO_4$ Standard | | | |
| | A | B | C | D | A | B | C | D |
| Jig concentrates.... | 76.2 | 76.6 | 76.6 | — | 76.0 | 76.3 | — | 76.0 |
| Vanner concentrates | 51.0 | 51.4 | 51.3 | 51.2 | 50.8 | 51.2 | — | 50.8 |
| Crude carbonate.... | 30.0 | 30.2 | 30.2 | 30.2 | 30.0 | 30.1 | — | 29.9 |
| Crude sulphide...... | 17.2 | 17.5 | 17.2 | 17.1 | 17.2 | 17.4 | — | 16.9 |
| Zinc concentrates... | 7.5 | 7.6 | 7.5 | 7.5 | 7.5 | 7.6 | — | 7.4 |

| Ores | Ammonium-Molybdate Method Filtering Hot Pb Foil Standard | | | | The Dichromate Method | | | | The Gravimetric Method | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | A | B | C | D | A | B | C | D | A | B | C | D |
| Jig concentrates ... | 76.2 | 76.8 | 76.8 | 76.5 | 76.1 | 76.2 | 76.4 | 76.5 | — | — | 76.4 | — |
| Vanner concentrates.. | 51.1 | 51.4 | 51.4 | 51.0 | 50.5 | 50.7 | 51.2 | 50.3 | — | — | 51.1 | — |
| Crude carbonate .. | 30.1 | 30.2 | 30.2 | 30.1 | 29.8 | 30.1 | 30.1 | 29.9 | — | — | 30.0 | — |
| Crude sulphide ... | 17.4 | 17.1 | 17.2 | 17.1 | 17.0 | 17.1 | 16.9 | 17.1 | — | — | 17.2 | — |
| Zinc concentrates .. | 7.5 | 7.6 | 7.5 | 7.5 | 7.5 | 7.4 | 7.4 | 7.5 | — | — | 7.4 | — |

The table shows closely concordant results. When $PbSO_4$ is used as the standardizing agent, the results average 0.3 per cent lower in total lead than when metallic lead is used, due to the fact that lead sulphate is slightly soluble in the menstruum. When metallic lead is used this error is compensated, for the same solubility occurs in the case of both standard and ore. The results of hot filtering give slightly high results, probably due to the fact that the standard is high, due in turn to a slight solubility of lead sulphate in hot solutions.

The chromate method was not recommended by the committee because "it requires two filtrations and the use of two standard solutions, which greatly increases the amount of manipulation." (The chromate method tested is not that of Low, which is gaining favor in this country.)

The gravimetric method is suggested as being useful for purposes of checking the results of the molybdate method.

The molybdate method is recommended. Standard ammonium molybdate solution contains 8.8 g. of the C. P. salt dissolved in 1 liter distilled water. Tannic acid indicator is made by dissolving 1 g. tannin in 300 cc. distilled water, to which 5 cc. glacial acetic acid is added as a preservative. Ammonium acetate solution is made by mixing 2 liters each of ammonia and distilled water, adding 2 liters glacial acetic acid and making faintly alkaline.

The solution is standardized by either lead sulphate or metallic lead; if the latter is used, the precipitate is to be filtered cold. The calculation of the standard, and of the amount of ammonium molybdate necessary to affect the indicator, is made as follows: Make two titrations on different quantities of lead or lead sulphate; subtract the lower quantity from the higher, and the corresponding lower burette reading from the higher. Calculate the standard from the remainders, thus getting the true standard, exclusive of the indicator. The amount of solution necessary to affect the indicator is then found by dividing the standard found into either of the weights of lead taken, which will give the number of cc. of solution required at that standard. The number of cc. found first by calculation is subtracted from the number of cc. found by titration, and the difference will be the quantity required by the indicator. This amount is to be subtracted from each burette reading on an assay before multiplying by the standard. Thus.

| Lead taken | Burette reading, cc. |
|---|---|
| 0.3549 | 35.3 |
| 0.1575 | 15.7 |
| 0.1974 | 19.6 |

$0.1974 \div 19.6 = 0.010071$ g. of lead—the true standard then $0.3549 \div 0.010071 = 35.24$ cc.;
therefore $35.3 - 35.24 = 0.06$ cc., which is the quantity required to affect the indicator, and which should be subtracted from a burette reading before applying the standard.

In the presence of large amounts of lime the method is modified by precipitating the lead from its ammonium acetate solution with ammonium sulphide, filtering, dissolving in nitric acid, evaporating nearly to dryness, neutralizing with ammonia, adding 30 c.c. ammonium acetate and titrating.

When antimony is present, carry the assay to the lead sulphate stage as usual, then dilute with water and add Rochelle salt to dissolve the antimony. Filter, wash and treat the lead sulphate as usual.

When tungsten is present, decompose the ore *thoroughly* with HCl; then add HNO and evaporate to about 5 cc. Dilute with 80 cc. hot water, filter and wash with boiling water. Treat the filtrate with $H_2SO_4$ and proceed as usual.

---

**Fuel Oil.**—Circulars 140, 141, and 142 of Messrs. Tate, Jones & Co., Inc., of Pittsburgh, Pa., deal with fuel oil. Circulars 140 and 141 describe this firm's appliances for handling and burning fuel oil, circular 142 gives fuel oil data from actual experience. One big advantage of oil as a fuel in boiler work, whether marine or stationary, is the fact that with oil the boiler can be pushed way beyond its rating and an evaporation obtained that would be impossible with coal. "Recent tests made by the U. S. Navy Department show that the heat-absorptive power of boilers is very great and that boilers can be pushed with little drop in efficiency far above their normal rating. The evaporation per square foot of heating surface has been increased from 3 lbs. of water from and at 212° to 15 lbs. of water with a drop of efficiency of only 10%." Data are given on the use of fuel oil in furnace work—direct-fired, reverbatory, regenerative, and crucible furnaces, also kilns, etc.

# New York Meeting of the American Institute of Chemical Engineers

## Report of the Proceedings and Abstracts of Papers

The sixth annual meeting of the American Institute of Chemical Engineers was held in New York City from Wednesday, December 10, to Saturday, December 13, the headquarters being at the Chemists' Club, where all sessions were held. The attendance was particularly good.

At the business meeting held on the morning of Wednesday, Dec. 10, the result of the annual election of officers was announced as follows:

Professor M. C. Whitaker, of Columbia University, is the new president.

Dr. A. C. Langmuir was elected a vice-president; Dr. John C. Olsen, of the Polytechnic Institute of Brooklyn, N. Y., and Dr. F. W. Frerichs were reelected secretary and treasurer respectively; Mr. H. M. Kaufmann was elected auditor and Messrs. Henry Howard, John C. Hebden, and I. P. Lihme directors of the Institute.

M. C. WHITAKER, PRESIDENT AMERICAN INSTITUTE OF CHEMICAL ENGINEERS

### Sanitation Control of the City of New York

In the professional session which followed, the first paper was presented by Dr. Ernst F. Lederle, Commissioner of Health of the City of New York, who extended the city's welcome to the Institute in behalf of the Mayor, and then discussed in a very interesting manner the sanitary control of the City of New York by the Department of Health, showing by lantern slides many views of the "yearly clean-up" which was attempted for the first time in 1913 in New York City and the methods of disposing of the immense quantities of various refuse collected from the streets and houses. The lecture was profusely illustrated by lantern slides.

### Recent Developments in Commercial Explosives

A paper by Mr. E. A. Le Sueur gave a sketch of the recent trend in explosives development. The most striking feature among the changes occurring in the field is the almost omnipresence of nitrate of ammonia. Although a salt of a hypothetical metal it breaks down into a gaseous mixture containing a surplus of free oxygen and no solid residue whatever and, insofar, is therefore peculiarly suited to employment in explosives. Unfortunately it is very hygroscopic and of deplorably low specific gravity so that but a comparatively small weight can be packed into a given cavity. On the other hand, its adaptability, within the above limitations, is remarkably wide, and it is associated with almost every ingredient known to explosives manufacture, and especially with nitro-glycerin. So wide is the present market for this material for use in explosives that practically the entire output of the gigantic Norwegian atmospheric nitrate works is now delivered in the form of nitrate of ammonia, and further important developments in the cheap manufacture of this compound are to be looked for in the very near future.

Perchlorates, and especially perchlorate of ammonia, have numerous advocates among the inventors, but so far do not appear to have entered the market to any very great extent. Perchlorate of ammonia is obviously, from its chemical formula ($NH_4ClO_4$) well adapted to act as an explosive itself and at the same time provide three atoms of excess oxygen to combine with additional material. Aside from any other considerations, it possesses the serious defect of liberating considerable hydrochloric acid or a mixture of the same with chlorine. The use of certain powdered metals in the mixture serves very largely to eliminate both of the above gases.

A most profound impression has been made in the explosives trade of late years by the nitro derivatives of toluol, and especially by the various commercial mixtures of di- and tri-nitrotoluol now on the market. The cheddites (practically mixtures of the higher nitrotoluols with chlorate of soda and a vegetable oil, preferably castor oil) have achieved considerable well-earned popularity, and the flood of current patent applications for explosives containing tri-nitro-toluol reminds one of nothing so much as of that which occurred some ten years ago for acetylene generators.

Bearing in mind that tri-nitro-toluol possesses certain of the properties, so far as explosive effects go, of nitro-glycerine itself; that it withstands water and is not affected by cold, and that it can be handled with absolute safety until blended with other materials that may increase its sensitiveness, it is not difficult to understand the enthusiasm with which it has been received by amateurs as well as by others in the explosives field. Aside from any admixture with other materials it forms, in the refined condition, an explosive of quite ideal properties for use in shells, torpedoes, mines and the like. In spite of its fierce and terrific disruptive energy and of an enormous speed of detonation, it is a safer material to handle, transport and store than, for instance, ordinary calcium carbide.

And, notwithstanding its inert behavior, it can be depended on absolutely to explode completely when exposed, in a suitable physical condition, to detonation from an adequate primer. Several European governments are now making extensive use of this intensely interesting compound. Owing to the fact that its constitution ($C_7H_5N_3O_6$) presents too little oxygen to combine completely with the carbon contents even to the monoxide form the result of explosion is the formation of a cloud of carbon particles which will presumably have its advantages in warfare both through marking the position of a shell at the instant of explosion and by obscuring the enemy's vision.

The liquid nitro-toluols are also finding an important use in connection with nitro-glycerine. They greatly lower the freezing point of the latter, contribute their quota to the explosive effect, and render the resulting explosive much safer than before.

In addition to the above compounds and many others (including the nitro-napthalenes, benzenes and xylols) the old stand-by, chlorate of potash, holds its own as a prime constituent of modern disruptive powders. It may be worth while to glance for a moment at the extraordinary thermo-chemistry of the chlorates and perchlorates, the same having a vital bearing on the matters of energy developed, sensitiveness and stability of certain explosive mixtures containing them.

Chlorate of potash disengages heat energy to the extent of 93,800 calories per kilogram molecule on formation from its elements, but potassium chloride disengages 105,700 calories, or 11,900 *more* than the chlorate. The addition of three atoms of oxygen to the chloride is accompanied by the absorption of energy to this latter extent, the formation reaction being endothermic. Perchlorate contains one-third as much oxygen again as chlorate, but instead of the addition being accompanied by a further absorption of heat, there is actually a disengagement of energy, accompanying the entry of this lone atom, of far more (19,900 calories altogether) than the entire amount absorbed when the first three atoms were added.

Chlorate stands ready to fall to pieces on scant provocation and, in doing so, give up not only three atoms of active oxygen to any combustible in the neighborhood, but 11,900 calories per kilogram molecule as well. Perchlorate, on the other hand, in spite of its higher degree of oxygenation, requires more energy to drag it to pieces than does the chloride itself, and, in consequence, forms a less sensitive and less energetic constituent for an explosive than the less oxygenated chlorate.

In the light of the above, and especially in view of the fact that the besetting trouble with most modern chlorate explosives is lack rather than excess of sensitiveness, it will be seen that plain chlorate presents certain large advantages over perchlorate for many explosives. This will help to explain the fact that, although modern electrochemical methods enable the ready production of perchlorates, the latter have not, so far, become serious competitors in the field of commercial explosives.

Mr. Le Sueur then dealt at some length with a chlorate explosive developed by himself and which has come into widespread commercial use.

In manufacturing this powder five parts of paraffine wax are melted and four of ground sulphur and twenty-two of nitrate of soda stirred into it; the mixture is allowed to cool and is then grained. The resulting material is called "mineral base." In spite of containing an oxidizing agent and combustibles it is completely inexplosive technically. It is finished to explosive by dusting 8 parts (to the above 31 of base) of powdered chlorate of potash over the grains.

The final material possesses a number of interesting features. Due to an extremely low speed of detonation it develops its power in a way peculiarly available for the requirements of many large applications such as heavy rock work, clearing land of stumps and the like; and, owing to the said low speed of detonation, its high effectiveness for these purposes, even compared with explosives possessing decidedly greater energy content, is quite surprising. Its insensitiveness is such that it withstands the impact of a steel tipped service rifle bullet fired from the regular service rifle with a standard charge behind it without response of any kind; although, due to its property of going out after being set fire to when the flame causing ignition is removed, it is possible that incipient ignition occurs during the passage of the bullet.

If packed hard it is impossible to explode it by any means whatever. On the other hand, loaded loose, it is an absolutely sure fire with a No. 6 detonator even when unconfined, and, for work in earth, as in removing stumps, it is necessary to bear in mind that confinement may be negligible. When well confined in large shots in solid rock, and especially if detonated with a stick of dynamite, it will withstand any reasonable amount of packing and still give a sure fire.

From its composition it will be obvious that it is non-freezing, and, indeed, owing to the paraffine wax incorporated in it becoming harder with increasing cold, it loses its porosity through being pressed into holes less readily cold than otherwise. With regard to stability, it withstands the international stability test (75 deg. C. for 48 hours) with indifference, whether with moisture added or not, and some millions of pounds have been used during the past seven years, and in some cases excesses over requirements have been stored by contractors in badly constructed magazines, occasionally for years, and there has never been any sign of heating or decomposition, incipient or otherwise.

The very low chlorate content and the fact that all the other materials are used in their crude commercial condition, together with the extremely simple process of manufacture, render the cost of this powder exceptionally low. It is known under the name of R. R. Virite.

With reference to the property which this explosive, in common with very many others, has of being more difficult to explode as its porosity diminishes, Mr. Le Sueur points out a certain important corollary which exists in a case where the insensitiveness when closely packed reaches the point it does in a case such as the one under discussion. If compressed forcibly to a specific gravity of about 1.45 it has been found impossible to explode by any amount of detonation, no matter what the degree of confinement. This in spite of the fact that a certain small amount of local combustion occurs where the material is in direct contact with the detonator.

The superficially paradoxical situation confronts us that the only condition in which the material can be exploded by hammering between hard surfaces is one in which it becomes insensitive to detonation from another explosive. By this is meant that, in order to cause explosion of the powder by hammering, it has to be packed to a maximum density before the pinching between hard surfaces necessary to cause explosion occurs. Of course, what happens when the material is hammered on an anvil is that any excess over what can be pinched down to the thickness of thin paper between hammer and anvil is forced aside and only the trifling amount of powder actually so pinched goes off, and it has hitherto been found impossible by any degree of practicable impact to communicate explosion from the quantity so pinched to the rest of the mass of powder. The importance of this peculiarity in securing freedom from accidents in any case other than where the powder is exposed to detonation from another explosive is obvious.

If we consider what is the fundamental difference between the blow of a hammer and that of a detonator we see at once why a mass of the explosive which refuses to transmit detonation however powerful (within the enormous upper limit experimented with) when in a dense (non-porous) condition, why such material may be readily exploded when in a porous condition by a detonator although a blow from a hammer can only have a local effect. The point is that, in the former case, the blow is struck so quickly that the explosive is hammered between the products of explosion of the detonator and, if this expression may be used, its own inertia, without having time for its porosity to be interfered with. The passage of a bullet exposes it to the same kind of a blow against its own inertia, but the swiftest bullet is so far inferior in speed to the velocity of the products of explosion of a detonator that it falls short, in the case of a powder of the class under discussion, of producing an explosion. There is also, of course, the essentially important feature, in the case of explosion by a detonator, of exposure to vastly greater heat than from the friction of a bullet or impact of a hammer.

The well-compressed material behaves, as previously stated, in a completely inert fashion to attempts to detonate it, but mere crumbling restores it to the explosible condition. It would seem as though a technical division on the lines of classification according to safety might well be adopted to embrace explosives that require outside detonation from another explosive in order to set them off.

Mr. Le Sueur finally discussed liquid oxygen as a constituent of explosives. Modern methods exist for producing this element in a state of high technical purity in the liquid form at a cost extremely low compared with its cost in the combined form in any of the chemicals employed in the explosives trade. So that completely smokeless and fumeless mixtures equal to 75 per cent dynamite can be made at a cost of about 2 cents per pound. As regards safety, explosives containing liquid oxygen stand in a class by themselves in one particular, *i. e.*, in the fact that, should a shot be missed for any reason, the charge presently becomes inexplosive through volatilization.

Of course, this is merely the merit which accompanies the greatest defect of these explosives. They must be used within a few minutes of being compounded. Nevertheless, this is by no means the absolutely prohibitive feature that might be expected, owing to two considerations, one of the numerous gigantic individual blasts that are necessary on certain heavy construction works (the time required for the charge to evaporate being comparatively long in such cases) and the other the fact that the addition of the liquid oxygen to the combustible portion of the charge may be made the last thing before firing. Mr. Le Sueur is rather firmly of the opinion that in the heaviest construction works of the future, especially where the so-called "coyote" shooting can be employed, liquid oxygen will play an important part.

In conclusion Mr. Le Sueur referred briefly to the hopes of the nitro-glycerine manufacturers that in synthetically prepared glycol may be found the solution of their bondage to the fluctuation of the corn and cotton seed crops. The production of glycerine depends considerably on the abundance or otherwise of pork and of cotton seed oil and the former depends largely on the corn supply. The stearine candle industry, another feeder to the high explosives maker, is not in a healthy condition, and altogether the situation of the dynamite manufacturers is not so completely free from anxiety in the matter of their glycerine supply as they might wish.

**Dr. W. M. Grosvenor** then presented briefly his suggestions on a "practical road to a standard catalog" of products of manufacturers for the chemical industries.

### Presidential Address

In an evening session on Wednesday, held again at the Chemists' Club, the retiring president of the Institute, **Dr. T. B. Wagner**, presented an admirable address on the effect of legislation upon chemical industries.

This address is printed in full elsewhere in this issue.

### The Clam-Shell Filter Press

A paper on the Sweetland clam-shell filter press was presented by **Mr. E. J. Sweetland** and illustrated by numerous lantern slides and demonstrations of a working model. We herewith give Mr. Sweetland's paper slightly abstracted.

That there is great room for improvement in the methods of filtration commonly employed cannot be doubted. The plate and frame filter press ordinarily used comprises anywhere from forty to one hundred filter chambers each of which must be cleaned individually by hand every time the filter is filled.

It was to eliminate the excessive amount of hand labor in cleaning filter presses that the filter under discussion was primarily designed, but as the construction was developed many incidental advantages of importance developed with it.

The single advantage in plate and frame filter presses that has kept them in favor is the fact that their peculiar construction affords a very large filter area in a comparatively small space. Filtration cannot be forced beyond a certain reasonable limit, when this limit is reached it is necessary to increase filter area to increase capacity. To endeavor to increase capacity by increasing pressure instead of filter area is futile, for excessive pressure merely presses the cake to a compact, almost impervious layer, and the object is defeated at once.

With this in view, the modern filter must not depart from a construction that permits of ample filter surface. Other things being equal, the capacity, and consequently the value, of a filter is proportional to the filter area.

The sluicing type of filter press is one example of a filter press construction that eliminates hand labor in cleaning. In this type the cake is disintegrated by a stream of water forced into each chamber. The cake thus liquefied flows to the waste reservoir, or dump. The usefulness of this method is limited for obvious reasons, principal of which is the need of recovering the cake as dry as possible in most processes.

The uses of filter presses are so varied that great flexibility is required. To be a commercial success the modern filter press must lend itself to the various requirements which may come up, and the construction made adjustable as far as possible.

#### CONSTRUCTION

The Sweetland filter has become known as the "clam-shell" type, due to the shell being in two parts hinged together to open and close somewhat after the manner of the clam shell bucket used on steam shovels.

The filter body comprises two semi-cylindrical members hinged together, one member being provided with an inserted gasket which seals the joint between the two to form a water-tight cylinder when closed. Fig. 1 shows an end and side elevation of the filter in closed position.

A plurality of openings is provided along the top to receive the stem or outlet nipple of the filter leaves. These outlets are spaced quite close together, so that the leaves may be closely spaced if desired, as is the case when thin cakes are to be formed; but the leaf spacing may be increased to any degree by taking out part of the leaves and stopping off the intermediate outlets.

Variable spacing is quite essential, for it is not always possible to ascertain in advance exactly what spacing will be best suited to the material; and further, there is always the possibility of the process being modified to change the filtering properties of the material and make a change in leaf spacing desirable.

The filter leaves are usually made of wire screen, well crimped to provide ample drainage. The screen is bound at the edges to stiffen the construction and protect the cloth. An outlet nipple with a side opening furnishes an exit for the filtrate and means of holding the leaf in the filter body. The filter cloth covers the entire metal construction of the leaf except the outlet nipple, and is held on either with metal clips or by being stitched around the edges.

The leaves are held in place in the filter by a cap nut which engages the top of the nipple and draws the shoulder of the leaf tightly against the rubber washer which fits in a recess inside the filter body. The side outlet of the nipple aligns with the filtrate delivery fittings on the outside of the press.

Fig. 2, which is a cross section of the filter body clearly shows how the filter leaves are held in place by the nipple at the top. Each leaf has separate outlet fittings comprising shutoff cock, glass delivery tube, etc. These fittings allow the operative to see the filtrate from each individual leaf as it flows through the glass, and any leaf that might become injured or require renewal of cloth is indicated at once by a turbid filtrate in the glass. In this event the shut-off cock governing the defective leaf is closed until the filter is opened and the leaf replaced. To remove a leaf only the cap nut has to be removed—the outlet fittings are not disturbed.

In the earlier designs of this filter the two halves of the shell were held in closed position by hand operated swing bolts. These were fairly quick and convenient to operate, but still left room for improvement. It was desired to modify the construction to an extent that would reduce the time to unlock and open the filter from a few minutes to a few seconds, if possible. This was accomplished by a very simple change in the construction. The hinges, which formerly took no strain while the filter was in locked position, were increased in strength and number and made to take the strain formerly taken by the swing bolts on the back of the filter body. To eliminate any possibility of breakage, the hinges are made of steel, which can be fully depended upon for strength.

What seemed the great problem in working out this improvement was the need of accurate hinge adjustment to take up wear in the gasket. This problem like many mechanical problems proved to be simpler than was anticipated, for it was solved by simply making the hinge pins into one continuous shaft reaching from end to end of the press, and turning the bearing which received all of the hinges on the upper member eccentric to the normal axis of the shaft. This construction not only affords adjustment, but makes adjustment of all hinges simultaneous by simply turning the hinge shaft slightly when adjustment is necessary to draw the upper and lower halves of the shell closer together as the gasket gradually flattens out from continued use. The shaft is held from turning by set screws, which are loosened when adjustment is made.

An eccentric shaft with swing bolts rests in babbitted bearings along the front of the upper half. Each bolt has an adjusting nut and lock nut for initial adjustment and for taking up wear. The swing bolts are tightened or loosened simultaneously, due to the eccentricity of the shaft, when the latter is turned through an arc of 180 degrees, and means is provided of swinging the bolts clear of the lugs on the lower half just at the point when they have loosened sufficiently to disengage themselves.

This arrangement makes it possible to open or close a filter press of moderate size in a few seconds. The lower half of the shell is poised with counterweights to facilitate opening and closing. A sectional view, showing hinges, eccentric shaft, etc., is shown in Fig. 26.

In large machines an eccentric shaft is used on both front and back, and a hydraulic cylinder operates the two simultaneously by means of a cross head and connecting rods. The lower member in this case is swung open and shut by a hydraulic cylinder at either end which is so arranged that the shell is opened so wide as to invert it and thus clean itself of any cake that might have fallen before it was fully opened.

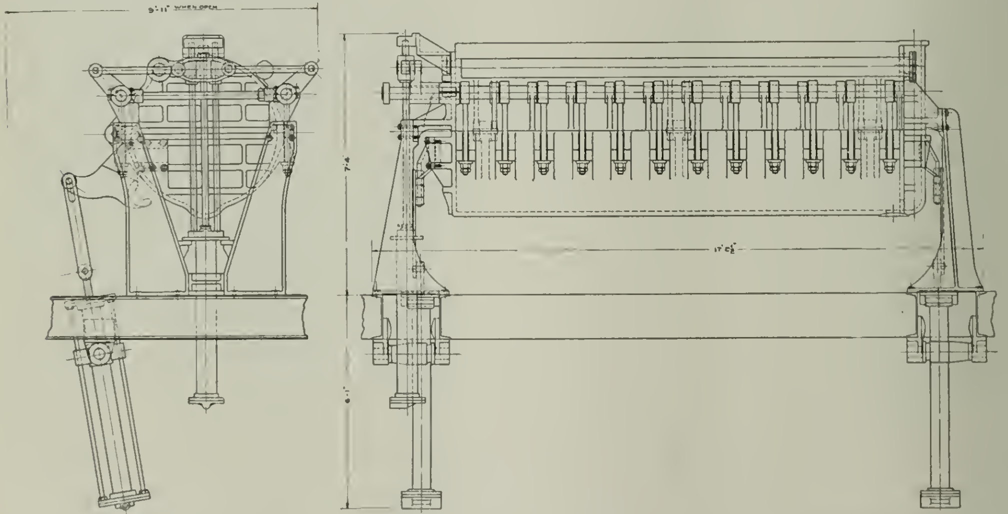

FIG. 1.—END ELEVATION AND SIDE ELEVATION OF CLAM-SHELL FILTER PRESS IN CLOSED POSITION

### OPERATION

In operating the filter the liquid to be filtered is forced into the filter body under pressure, expelling the air and entirely submerging the filter leaves. The liquid filters through the cloth and deposits the suspended solids on the outside of the leaves, forming the "cakes." Filtration continues until the cakes on adjacent leaves are separated only by a narrow space which may vary in width from 1/8 inch upward. When the cakes are formed to the proper thickness the wash water valve is opened and sludge valve closed simultaneously.

The wash water enters the space between the cakes forcing the small quantity of unfiltered sludge to deposit its solid component upon the cake surface. The space between adjacent cakes is now occupied by water, which being under pressure, percolates through the cakes, driving the strong liquor ahead and effectively displacing it until the cakes are washed to the desired degree, as indicated by frequent tests of the effluent.

Mr. Sweetland enlarged upon the subject of washing the cakes, for therein lies a great difference between his and other leaf filters. It should be noted that there are no chambers or containers to be packed solidly full of cake. The spaces between the leaves are not packed solidly full, but a cake is deposited on the surface of each leaf and these cakes are allowed to build up until only a narrow space remains between them, and in this space lies the secret of successful automatic discharging of the filter and efficient washing.

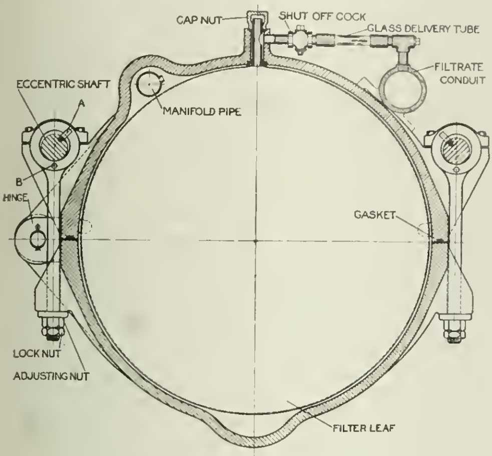

FIG. 2.—CROSS SECTION OF FILTER BODY

The cakes have been formed under equal conditions, the sludge being evenly distributed and the pressure equal throughout the filter chamber; therefore the cakes must be of even thickness and density, and must wash evenly. That this actually occurs has often been demonstrated by testing samples of the washed cake from various parts of the press.

All filters of the leaf type wash by "direct contact" methods; that is, the wash water is in direct contact with the cake; but the methods of washing that have heretofore been practiced with leaf filters, whether vacuum or pressure, are indeed anything but direct.

The usual method of forming and washing the cakes on filter leaves is as follows, assuming that the cake has to be washed first with weak liquor and then with water: Fill filter tank; deposit cake on leaves; withdraw excess solution; fill filter tank with weak solution; wash cakes with weak solution; withdraw excess weak solution; fill filter tank with water; wash with water; withdraw excess water; discharge cakes from leaves.

Here are ten distinct operations, which are still further complicated by the fact that the cakes will not cling to the leaves unassisted, but must be held on with either compressed air or vacuum during the time each quantity of excess is withdrawn. Mr. Sweetland did not dispute that the cakes can be washed well by this method, but raised the point that it is an extremely round-about method of accomplishing a simple object. Most of the power consumed is not devoted to filtration, but to transferring solutions, much of the time is not devoted to filtering, but to waiting for transfers to be made, and the operative is kept busy manipulating valves.

The delay in filtering necessitated by the many transfers materially cuts down the duty of the filter, and the process becomes a complicated one, requiring many tanks and much accessory apparatus to take care of excess solutions.

Nor is this all. The transfers of excess solutions referred to introduce other complications. The cakes must be supported upon the leaves at all times by pressure. Air pressure (whether produced by suction or otherwise) must be used during the transfers. If too much pressure is used, the cake will be cracked (due to the shrinkage of partial drying) and the wash water will "short circuit," that is, pass through the channels formed by cracking. If too little pressure is used, all or part of the cakes may fall from the leaves, which would preclude the possibility of efficient washing. Lastly, if the cakes are of a fine slimy character, the partial drying during the transfer packs the particles of slime, and makes it less pervious than ever to the passage of wash water.

The origin of the many complications cited above is traced directly to void or "dead" space in the filter tank or chamber which contains the filter leaves. If there were no dead space there would be no excess solutions, and consequently none of the complications which attend them.

The "clam-shell" construction of filter body has no void space. It contains nothing but the filter leaves and manifold pipe. When the filter leaves are loaded with cake the entire filter chamber is full except the feed channel for distribution along the bottom, and the narrow space between the cakes for the entrance of wash water. There is, therefore, no excess solution to handle. Filtration is continuous from the time cake forming is commenced until washing is finished, and the process of filtering and washing is reduced to the simplest possible terms.

When washing is finished the cakes are partially dried with compressed air, the lower half of the filter body is swung open and the cakes are dumped into a car or conveyor underneath. To assist the cakes to dislodge from the leaves, the current is reversed by turning steam or compressed air inside of the leaves, which not only causes the cakes to drop off, but benefits the cloth by keeping the pores open.

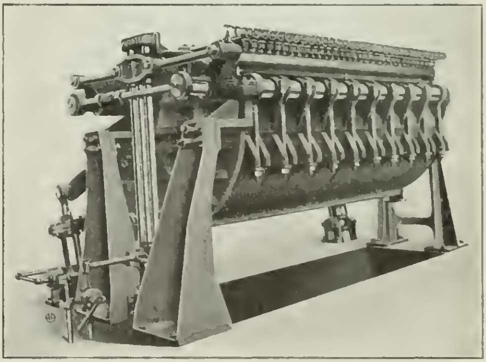

FIG. 3—HYDRAULICALLY OPERATED SWEETLAND SELF-DUMPING FILTER CLOSED

For the benefit of those who insist that better washing can be obtained by draining the filter body before introducing wash solutions or water, Mr. Sweetland pointed out that the filter construction here described offers every facility for carrying out this method, if desired; but, after installing many of them, large and small, under widely varying conditions, and seeing trials made both ways, he strongly advocates the direct method without withdrawing solutions.

If the material is very slow-filtering and the space between the cakes wide, then it is better to introduce the wash water through the manifold pipe and let the water entering the top fill the chamber by downward displacement, forcing the excess solution out of the drain valve at the bottom. The water being lighter than the sludge, it does not mix with it, but floats on top during displacement. In this case filtration is continuous, pressure is maintained in the chamber, no time is lost, and the cakes are constantly submerged.

Mr. Sweetland then discussed why the body of this filter was designed cylindrical instead of square. Obviously the principle could be carried out in a filter body of square or rectangular section. The reasons for cylindrical construction are: The cylindrical construction affords great strength, whereas any shape with straight sides would require so much reinforcement to give it the necessary strength as to make it cumbersome and awkward.

In the cylindrical construction the leaves are exposed to view by simply swinging the body open.

A circular leaf is conveniently supported from one point and is very strong and light.

If the chamber were square the leaves would be inaccessible, or else would have to be lifted out with the cover to discharge, and this would involve mechanical difficulties.

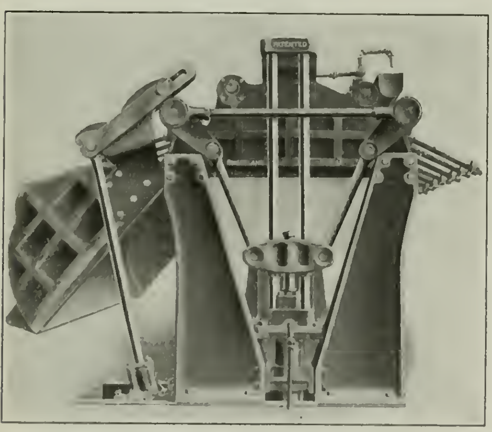

FIG. 4.—END VIEW OF FILTER OPEN

The circular form of leaf does not involve as much waste in filter cloth as might be imagined. There is to be sure a slight waste of cloth cut from the corners, but most of this has an important use in reinforcing the cloth at the edges of the leaf. On the other hand, a large percentage of the cloth used in plate and frame presses is not used for filtering, but to form a joint between the frames. If we figure it out in any case, we find that the percentage of cloth purchased that is utilized as filter medium is about the same in either case. In fact the cost of cloth per unit of work done is much less in the case of the leaf construction, because the capacity per square foot is greater, and the cloth is not injured by being squeezed between the frames.

As to filtering mixtures containing coarse particles, these offer difficulty in any type of filter, due to the coarse particles settling to the bottom, making the bottom of the cakes more porous than the top and resulting in uneven washing. The remedy for the trouble is to keep the contents of the filter chamber in a state of agitation. To accomplish this the feed pump is provided large enough to supply the necessary pressure for filtration with additional capacity enough to permit a restricted overflow to run from the manifold pipe back to the supply tank during filtration.

### FILTER AIDS IN FILTERING MATERIALS CONTAINING A GUMMY RESIDUE

New light is being thrown on the subject of filtration with almost every new installation, and problems are being successfully solved that appeared at the start to be impossible of solution. To cite an instance: A sample of a heavy viscous liquid was submitted for test. It contained a gummy residue that blocked the filter cloth from the start, and the rate of flow of filtrate per square foot of cloth was but a few cubic centimeters per hour, and the cloth became so coated as to defy cleaning by any practical method.

As the solution only was required, and the residue was worthless, there seemed to be no objection to adding some inert granular substance to the liquid as an aid to filtration. A series of experiments was undertaken, adding various "filter aids" to the fluid, and the outcome of this work was that an average rate of filtration of three gallons per square foot of cloth per hour was obtained and the gummy residual matter was sufficiently broken up to permit the filter cloth to be readily cleaned by reversal of current. Upon completion of the tests, a filter was installed in the plant and has fully demonstrated the practicability of the method on a working scale.

It was found that any one of several substances could be used as an aid to filtration, among which are fine sand, fuller's earth, kieselguhr, sulphate or carbonate of lime, sawdust, wood pulp, etc.

It is not argued that such methods are applicable to all cases, but there are unquestionably many problems that will find solution in similar schemes, which make possible rates of filtration such as are usually obtainable only in sand filters, with the added advantage that the leaf filter offers an enormous filter area in a small space, combined with extraordinary ease of cleaning.

Another method of filtering materials containing a gummy residue that tends to choke the cloth is that of depositing a protecting layer on the cloth before commencing filtration. For instance, we may first fill the filter body with a very thin slurry of carbonate of lime and filter this mixture for a few seconds until a film of lime, say 1/32″ in thickness has been deposited. This coats the cloth as completely and evenly as a deposit could possibly be made. The lime slurry is then drained off and filtration commenced. The coating of lime forms a complete film between the cloth and gummy residue, so the latter never even touches the cloth. When ready to clean the cloth the reversal of current is effective, because the coating of lime breaks away readily.

It is frequently asked how we can tell when cakes of sufficient thickness have been formed, especially when the material filters and builds up the cake rapidly. This is not as difficult as would be imagined. The usual way is to work at a given pressure, say forty pounds per square inch, and pump for a certain number of minutes, determined by practice to form the required cake. Another way is to pump a certain number of inches from the supply tank for each charge. As in all processes, the operative soon becomes expert and can judge from the general conduct of the filter when the charge is sufficient.

The usual skepticism which attends the introduction of any new machine was encountered at first, but so many installations are now in successful use as to establish fully the usefulness of the methods described. A noteworthy point is the fact that many of the filters of the type in use are of much larger size and capacity than it is found practicable to build filter presses. Many have been built with a capacity of 133 cubic feet of cake per charge and several others ranging from 80 to 120 cubic feet per charge. One especially large one was built which dumps over 25 tons of cake per charge.

That this apparatus is now far beyond the experimental stages is demonstrated by the fact that a large beet sugar factory in California installed three large hydraulically-operated machines for the 1913 campaign. They were installed almost at the last minute before the campaign started and were at once placed in service at full capacity, and no difficulty was encountered, in spite of the fact that none of the employees who operated the machines had ever seen one before. The time required to open, clean and close one of these filters is about five minutes, which minimizes labor to such an extent that one operative can take care of several large machines, even though each machine has to be cleaned hourly.

### Electrolysis of Chloride Solutions with a Mercury Cathode

In a brief paper by Mr. E. A. Le Sueur reference was made to the author's well-known pioneer work on the electrolytic production of caustic soda and chlorine started in 1888. While in this work Mr. Le Sueur developed the diaphragm process, his first experiments in 1888 were made with a mercury cathode.

The point emphasized by the author is that with a view to getting the sodium the worst possible place is to deposit it on top of a layer of mercury exposed to contact with the solution. The point is that, although sodium dissolves in mercury, the initially formed amalgam is of very low specific gravity compared with mercury itself and naturally tends to stay on top of the latter. The alternative occurred to Mr. Le Sueur to use the under side of the mercury as the cathode, the upper side being completely exterior to the electrolyzer as such, with the idea that the sodium, as fast as it was delivered to the under side, would bob up to the upper side and be thereby removed from relation with the electrolyzer and its contents.

This he proceeded to do, using a horizontal square frame of paraffined pine wood, a supporting sheet of a special cotton fabric carried by the under side of said frame, and additional support supplied to the fabric by a paraffined wood grating. Mercury was placed on the fabric to a depth just sufficient to cover it completely and a current supplied from a primary battery of three large bichromate cells between a carbon anode and the under side of the mercury, saturated salt brine being the electrolyte. As far as it went this experiment was successful, and the author is convinced that this general principle would work up to the best possible type of mercury cathode electrolyzer.

"In the light of the principle so clearly grasped in connection with the above quarter century old work, it is curious to note, in Wilderman's address before the International Congress last fall, the repeated remarks on the disadvantages all processes previous to his have labored under of putting the light sodium on the top layer of mercury and leaving it there."

### New Filter Press

The first paper of the Friday morning session was presented by Dr. **Alfred Burger** on a new filter press which appears to have some important advantages over the old chamber press. It is really a novel and very ingenious system of piping in connection with the filter press. The principle of washing is the same as in the Sweetland press, but the method is different and Dr. Burger's system can be attached to any chamber press. The following figures were given, the figures in row No. I referring to an old chamber press, those in row No. II to the Burger press, and those in row No. III to a filter press of the leaf type.

| | Washing efficiency | Final $H_2O$ left | Pound of dry [illegible] per filter per sq ft per hour |
|---|---|---|---|
| I. | 20% | 60% | [illegible] |
| II. | 60% | 28% | 3 |
| III. | [illegible]% | 56% | 3.5 |

### Ozone

Dr. **A. Vosmaer** then presented a very interesting lecture illustrated by lantern slides on ozone, its manufacture and use. The paper consisted of three parts, dealing respectively with the methods of manufacture, the properties of ozone, and its uses, especially for sterilization of water, for deodorization of air, and the applications of ozone in the chemical industries.

Since Dr. Vosmaer is writing a special elaborate series of articles for this journal, discussing the subject in great detail, it must suffice here to refer the reader to these articles. The first two articles of this series appeared on pages 623 and 705 of Vol. XI, 1913, and a third article will be found elsewhere in the present issue.

In the discussion Dr. Franklin spoke vigorously on the stir caused by the recent agitation of medical circles against ozone. Their experiments as to the fact that ozone does not kill bacteria in air were perfectly right, but did not refute in the least anything that had been claimed by intelligent and reliable advocates of the treatment of air by ozone.

### Wood Turpentine Industry

A paper on the status of the wood turpentine industry by **E. H. French** and **James R. Withrow** was then presented by Dr. Withrow.

This paper outlined the present status in this industry and compared the same with that of gum turpentine. Emphasis was laid upon reasons for past failures in the business and upon the fact of its economic necessity for the utilization of cut-over timber lands.

The various processes for producing wood turpentine which have been in extended use, namely, the steam, solvent, alkali, bath, and distillation processes were discussed, giving general data derived from commercial operations as to yields, value of products, cost of operation and construction. The advantages and future possibilities, together with the disadvantages of each process, were discussed, but no particular process was recommended to the exclusion of others. The conditions under which only each may operate with profit were indicated.

As many of these figures in this paper contain heretofore unpublished information the paper will be published in full in our February issue.

The paper was discussed at some length by Dr. Wagner and Mr. Chute.

### Symposium on Welfare and Safety Work in the American Chemical Industries

In the evening of Friday the members of the Institute were the guests of the New York Sections of the American Chemical Society, the American Electrochemical Society, and the Society of Chemical Industry, the program being a symposium on welfare and safety work in American chemical industries.

Miss **Florence Hughes**, member of the general staff for sociological work of the New Jersey Zinc Company, gave a general outline of organization and development of neighborhood work at Palmerton, Pa., of the welfare work in progress at Austinville, Va., and De Pue, Ill., and emphasized the consistent policy as applied to safety and hygiene in care of workmen. Several conclusive statements were made as to relation between settlement work and the industrial and social problems.

Mr. **Howard Lyon**, of the experimental department of the Welsbach Company, discussed in his paper safe conditions of labor, fire protection, means for promoting the health of employees and treating the injured, the establishment of an employees' relief association, and provision for æsthetic and cultural betterment.

Mr. **Charles P. Tolman**, chairman of the Manufacturing Committee of the National Lead Company, dealt with sanitary improvements in the manufacture of white lead, both in the corroding yard and the mill, welfare equipment and welfare work, safety devices for the prevention of physical injury, and emphasized the human element in work of this kind.

Dr. **Francis D. Patterson**, director of the Department of Sanitation and Accident Prevention of Harrison Bros. & Co., Inc., spoke of the sanitary measures, devices and improvements, and the means for the prevention of accidents, adopted by this company.

### Excursions

A very full program of excursions was provided which included a visit to the Barber Asphalt and Paving Company of Maurer, N. J., a whole-day excursion on Thursday to the plant of the Sanitary Utilization Company at Barren Island, with inspection of the Willard Park Hospital group of laboratories of the Department of Health of the City of New York, and excursions on Friday afternoon to the experimental electro-plating plant of Hanson & Van Winkle Co. at Newark, N. J., and the Atha Works of the Crucible Steel Company of America, at Harrison, N. J. On Saturday morning the chemical engineering laboratories at Columbia University were inspected.

The International Exposition of Safety and Sanitation, held under the auspices of the American Museum of Safety at the new Grand Central Palace, also attracted many members of the Institute.

A well attended and greatly enjoyable subscription dinner was held on the evening of Friday at the Chemists' Club, when the Institute medal was presented to Dr. Frerichs.

The place of the next meeting has not yet been determined, but it will probably be either Buffalo or Troy, N. Y.

## Analyses of Coals in the United States

The report just issued by the United States Bureau of Mines as Bulletin 22, entitled "Analyses of coals in the United States, with descriptions of mine and field samples collected between July 1, 1904, and June 30, 1910," contains the analyses of 5000 samples of coal taken from 1500 coal mines and prospects situated in the various coal fields of the United States. Not only all of the important fields are represented, but practically all of the more important mining districts.

The purpose of the bureau in compiling and publishing this information is to present reliable information regarding the chemical composition and heating value of the coals. The samples of coals were collected by experienced men according to a definite and uniform system, and were analyzed under carefully controlled conditions, so that there might be no question as to the relative merits of the different coals so far as this can be determined by chemical analyses and determination of heating values.

An increasing proportion of the coal consumed in the power stations and the larger manufacturing plants of the country is now being purchased under specifications based on chemical analyses and calorimetric determinations of heat units. In the purchase of fuels many matters that have been left to chance are now carefully investigated.

It is the aim of mechanical engineers to construct furnaces and to arrange the heat absorbing surface in a furnace with reference to the peculiar character of the fuel which is to be burned. Noting the composition of the fuel and constructing the furnace with reference to it, he can assure efficient and smokeless combustion. Moreover, in any particular market, the choice of coal generally is limited by its quality and by freight rates to one or two fields in which the character of the coal bed is comparatively uniform.

Having on hand a representative analysis of the coal from a given bed in any particular district, the engineer can determine whether the coal he receives comes from the bed and the district stated, and whether it is being prepared for market as carefully as it should be.

Wide variations in the composition and heating value of the coals from different districts and from different beds make analyses that are comparable, because of the care taken in sampling and analyzing the coal, almost indispensable to engineers having to install boiler or gas-producer plants in different cities, and also to railroads and steamboat companies, and to the engineers and purchasing agents of the various departments of the United States Government.

The report just issued by the Bureau of Mines is in two parts, one giving the methods used in collecting and analyzing the samples, and the results of the analyses, and the other giving the exact location from which each sample of coal was taken, together with a description of the characteristic features of the coal bed at the point of sampling, the nominal capacity of the mine, and such notes on the preparation of the coal as might be useful to consumers.

The data contained in these two volumes is not equalled in scope and detail and in value for comparative purposes by the figures that have been published by any other coal-producing country in the world. The governments of some of these countries have published analyses of coals from different mines and from different districts, but, with few exceptions, the samples of coal were not collected and analyzed under a uniform system that would make the results comparable in all respects, and no country has attempted to publish such a large number of analyses that would be comparable because of the care taken in collecting and analyzing the samples.

Copies of this bulletin may be obtained by addressing the Director of the Bureau of Mines, Washington, D. C.

## A Large Electric Steel Furnace Installation

The American Iron & Steel Company, of Lebanon, Pa., has just closed a contract with Siemens & Halske, of Berlin, Germany, through their representative, Dr. K. G. Frank, of New York City, for what will be the largest single electric furnace installation in the world.

The company has been making an investigation of electric steel-making in this country and Europe and has decided upon the construction of two 20-ton induction furnaces of the Frick type. The furnaces will be of double-ring type and will run on five cycles, single phase, and about 5000 volts. The power requirements will be about 1800 kilowatts each. Two new generators will be installed by the company to serve this need.

**The Pacific Tank and Pipe Company** have moved their San Francisco sales offices from Fifth and Bryant Streets to their old offices, which have been completely refitted, at 318 Market Street, San Francisco.

**Fuller's earth** is the subject of *Bulletin* 71, Bureau of Mines, and deals with the properties, production and preparation of the material for commercial use. Laboratory methods of testing the substance are given.

## Recent Chemical and Metallurgical Patents

### Copper, Lead and Zinc.

**Hydrometallurgy of Copper.**—The accompanying flow-sheet shows diagrammatically the process of Mr. FREDERICK LAIST, of Anaconda, Mont., for the treatment of low-grade copper ores and tailings, in which the metal may be in the form of oxide, carbonate, silicate or sulphide, or in any form in which it may be dissolved and precipitated by $H_2S$. This process has been devised for the treatment of sand tailings at Anaconda, and a commercial-experimental plant of 80 tons daily capacity is now in operation.

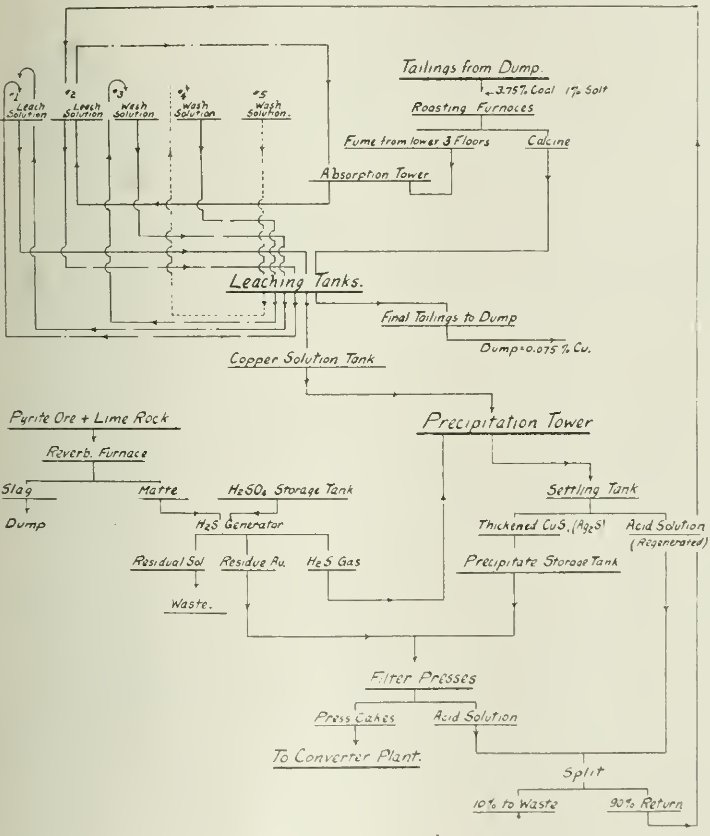

FIG. 1.—FLOW SHEET OF LAIST'S PROCESS

Some of the details of the process, as relating to sulphide ores containing copper and silver, are given herewith. The ore is first subjected to an oxidizing or sulphating roast in a McDougal roaster. The furnace is of special construction. The upper three hearths are devoted to the oxidizing roast, and the lower three to a chloridizing roast, about 1 per cent of salt being added. The resulting products are cupric chloride, silver chloride, ferrous chloride and ferrous oxide. In the chloridizing roasting process some of the copper passes off as fumes of copper chloride, together with some hydrochloric acid. These fumes are drafted to an absorption tower where they are absorbed in water and returned to the leaching solution.

The calcine resulting from the oxidizing and chloridizing roast is leached in vats with a solution of water with about 5 per cent $H_2SO_4$ and 10 per cent NaCl. This solution dissolves the metals, and contains copper chloride, copper sulphate, silver chloride, and certain impurities such as iron and aluminium sulphates and chlorides. The solution is then drained off and precipitated with $H_2S$, yielding a precipitate of copper and silver sulphides. The sulphuric and hydrochloric acids are regenerated and used again. To prevent the accumulation of iron and aluminium salts in the leaching solution, part of it is continuously run to waste.

Sulphuretted hydrogen as a precipitant has certain advantages over electrolysis, in that no expensive equipment is required, and its action is not affected by the ordinary impurities of the solution. The gas is generated from an iron matte or copper-iron matte made by smelting pyrite or pyrrhotite ore, preferably containing gold and silver. This matte is readily decomposed by $H_2SO_4$, yielding $H_2S$. Ferrous sulphate also is formed and wasted. The residue contains the valuable metals, and is combined with the copper precipitated from the solution.

Two leach solutions and three wash solutions are shown in the flow-sheet. These are used in such a manner that the progressive increase in strength of the several wash solutions prevents an undesirable weakening of the leaching solution with which the wash solutions mingle. Various forms of apparatus may be used without affecting the process as long as the successive steps described are followed. (1,076,833, Oct. 28, 1913.)

**Another hydrometallurgical** process for copper, making use also of electrolysis, is that of Mr. HENRY S. MACKAY, of Riverside, Cal. The principal features of this process are (1) the preparation of the solvent ferric chloride, by electrolysis of sodium chloride with iron anodes; (2) the agitation of the ore with this solvent; and (3) the electrolytic deposition of the copper, with regeneration of the active solvent. (1,074,274, Sept. 30, 1913.)

**The use of electrolytic iron** as a precipitant of copper from solution is one of the features of a process patented by Mr. ALBERT DAVID, of Brooklyn, N. Y. The inventor leaches a copper ore with ferric chloride solution, precipitates the copper with electrolytic iron, and passes the impoverished solution to an electrolytic vat in which iron is removed for use as a precipitant. The solvent is regenerated in the process of electrolysis, and returned for further use. Certain auxiliary reagents are used to facilitate both the leaching and electrolysis. One of these is an alkali chloride; another is hydrochloric acid, and a third is a soluble sulphate such as sodium sulphate. If the original ore contains little or no soluble iron, the solution slowly becomes depleted of this metal, and some must be added from an outside source. If an excess of soluble iron is in the ore, some of the metal must be discarded from time to time. (1,075,093, Oct. 7, 1913.)

**Combination Smelting and Converting Furnaces.**—In Fig. 2 is shown a longitudinal sectional view of a combination smelting and converting furnace for the treatment of copper ores, patented by Mr. EMIL KNUDSEN, of Mühlbach, Austria-Hungary. The device is a tilting furnace in the form of a cylinder. At one end the bottom is provided with a recess 1, receiving blast pipes 2. This part of the furnace is of the Bessemer type. The part between the recess 1 and the opposite end 3 is constructed so that the bottom slopes toward the recess. There are two top openings, as shown, one being numbered 4 and the other 6. Number 6 is out of alignment radially with the opening 4, so that when the furnace is tilted molten material will escape through 4 without discharging anything through 6. In operation the ores charged through 6 are smelted and run onto the Bessemer recess 1, where copper is produced in the usual manner. (1,075,214, Oct. 7, 1913.)

Another form of furnace designed for similar purposes is shown in side elevation in Fig. 3, being the invention of Mr. GEORGE MITCHELL, of Los Angeles, Cal. It consists of a smelting hearth 2 and a converter 3, the latter being located at one end of the furnace. At the opposite end is the stack and a steam boiler adjacent the stack if desired. Burners for oil or gas are located at 6. After smelting has progressed up to the point where there is sufficient matte to convert, the heat generated in that process will be of material assistance in carrying on the smelting operation. (1,074,282, Sept. 30, 1913.)

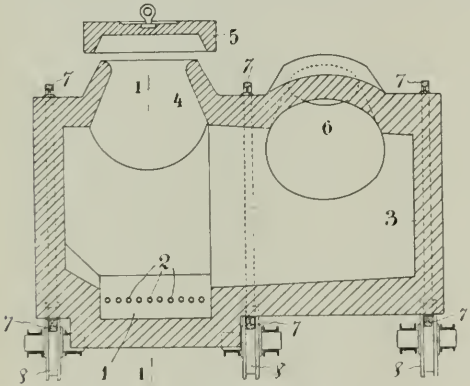

FIG. 2.—KNUDSEN COPPER FURNACE

**Zinc Smelting Under Pressure.**—Various attempts have been made to smelt zinc ores in cupola furnaces, but have generally been unsuccessful. The vapor of metallic zinc has been reoxidized before it could be collected, and the fluxing materials have prevented precipitation. According to a patent granted to Mr. ELISHA B. CUTTEN, of Erie, Pa., the inventor proposes to smelt zinc oxide free from gangue, and effect the reduction in a low blast furnace in a reducing atmosphere under pressure. Zinc oxide, produced by some suitable process, is briquetted with fuel, charged into a furnace heated by gaseous or liquid fuel, and smelted under a pressure of from 20 to 60 lb. per sq. in. The fuel is injected in such quantity as to produce reducing conditions. The furnace would be operated intermittently, and metallic zinc drawn at the end of the operation. (1,080,102, Dec. 2, 1913.)

**Chloridizing Complex Ores.**—A modification of the general proposal to chloridize complex sulphide ores by treatment with dry chlorine, is patented by Mr. TORMOD R. FORLAND, of Broken Hill, N. S. W., Australia. The inventor has discovered that volatilized chlorides can be separated by fractional condensation, and he proposes subjecting the distilled chlorides to successively lower temperatures, thereby separating the metal salts. Thus, lead chloride would condense at a temperature just under 900° C., zinc chloride just under 730°, etc. The fractions would be collected in a molten state or as sublimate in several condensers, and would be removed for electrolysis. The end products would be metals and chlorine, the latter being returned to the treatment for more ore. By varying the temperature of the distilling furnace, various fractions could be driven off and condensed. (1,078,779, Nov. 18, 1913.)

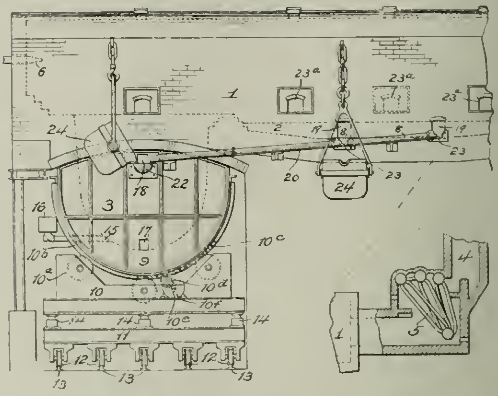

FIG. 3.—SMELTING AND CONVERTING FURNACE

### Metallurgical Furnaces.

**Heating Furnace.**—An improvement in furnaces of the type used for heating metal bars or rods, is shown in Figs. 4 and 5, being the invention of Mr. WALTER S. ROCKWELL, of New York City. One object of the invention is to utilize the waste heat of the escaping gases to preheat the air used for combustion, and to construct this preheater in the form of a shield to protect the operator. The figures show a furnace with a heating chamber 1 and working opening 2. Heat is supplied through burners 10 on each side of the chamber, fuel being delivered to the burners through pipes 11. Air is

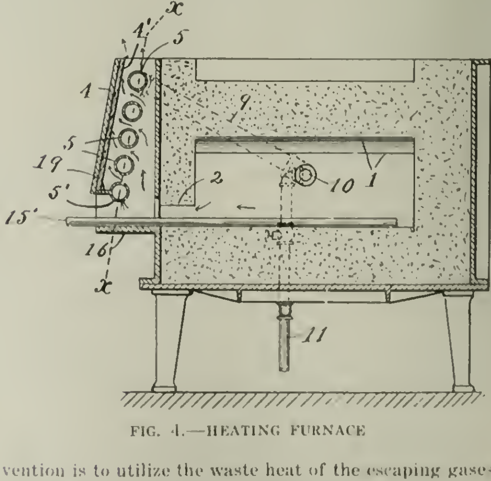

FIG. 4.—HEATING FURNACE

supplied to the burners through pipe 8, passing first through pipes 5 connected at their ends with headers 6, 7. A shield 4 is placed in front of pipes 5, and the entire arrangement of shield, headers and pipes forms a preheater for air and a protection to the operator. Hot air issues from the preheater through pipes 9 leading to the burners. (1,079,266, Nov. 18, 1913.)

### Iron and Steel.

**Reduction of Ores.**—The specifications of a patent recently granted to MR. JAMES A. MCLARTY, of Toronto, Ontario, Canada, disclose the inventor's idea of reducing oxide ores by subjecting them to the action of reducing gases at a temperature below a red heat. In carrying out his process he supports the ore on a suitable grate above a bed of incandescent coke. Air is admitted freely to the coke fire, so that the product of combustion is practically all $CO_2$. At a point between the bed of fuel and the grate supporting the ore, he injects a spray of a liquid or gaseous hydrocarbon, or a finely powdered carbohydrate, or any other material that will reduce the $CO_2$ to CO and yield hydrogen. The temperature of the gas falls during this reaction, but is still high enough (750-800°F.) to permit reaction with the ore. The reaction takes place at a temperature above that at which sulphur and similar impurities will sublime from the ore, but below that at which sulphur or carbon will combine with the iron. Apparently the product of the reaction cannot be molten, and although the specification does not mention the physical condition of the product, it may be assumed to be "metallized" in solid form. (1,079,788, Nov. 25, 1913.)

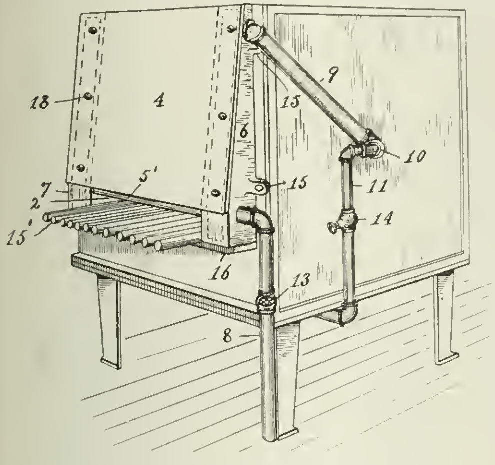

FIG. 5.—HEATING FURNACE

**Nodulizing Kiln.**—A form of kiln for nodulizing iron ores, in which the formation of sintered rings of ore is said to be prevented, is the subject of a patent granted to MR. LEWIS P. ROSS, of Standish, N. Y. The kiln is of the usual rotary-tube type, inclined to assist the travel of ore from feed to discharge, and being fed with finely divided ore at the upper end and with a fuel flame at the lower. The point of distinction lies in the fact that the lower end of the kiln, about one-third of the total length, in which the adhesive rings of ore usually form, is separate from the upper portion, and whereas the upper portion rotates continuously, the lower part is merely oscillated, being actuated by a reversible motor. The result of the oscillatory action is that the adhesions of ore form in the shape of a crescent instead of a full circle. The thickest part of the adhesion being at the top of the kiln, the mass falls of its own weight and thus removes the obstruction. (1,076,705, Oct. 28, 1913.)

### Gold and Silver.

**Filter-Leaf and Method of Dislodging Cake.**—In two patents granted to MR. CHARLES BUTTERS, of Oakland, Calif., the inventor suggests improvements in the construction of vacuum filter-leaves, and in the method of discharging the filter-cake from them.

The new form of filter-leaf consists of a rectangular frame of wooden members, in which shallow channels are formed on each face for receiving wooden strips by which the filter cloth is secured to the frame. The central pervious member of the filter is cocoa matting, and the outer filtering medium is drilling of light weight. In making the filter, a sheet of drilling is first attached to one side of the frame by means of the wooden strips inserted into the grooves or channels, and held in place by tacks or nails. Then the cocoa is laid in the frame, and the other filter cloth attached on the opposite side of the frame. Vertical strips of wood spaced at equal intervals along the opposite faces of the leaf are held in place by metal holders on the wooden frame, and are bolted together at their mid length. These serve to give rigidity to the leaf. The method of construction is simple, and avoids the necessity of stitching a filter bag in the usual manner. The leaf is easily demountable, and thin, relatively cheap filter cloth can be used, discarded and renewed at frequent intervals.

The improved method of dislodging the filter cake is apparently an effort to get away from the use of compressed air or liquid applied to the inner surface of the filter, in a direction reverse to that of filtration. Each filter leaf is provided with a header pipe, perforated on its under side with ¼-in. holes 3 in. apart, and supported well above the vacuum header. Through this perforated pipe water can be forced under pressure and caused to flow downward over the filter cake, thereby causing it to fall from the filter cloth. It is essential to the easy operation of this method that the filter cloth be smooth and that the cake be as dry as it is possible to make it by vacuum. In operation, after the cake has been formed and washed, it is suspended in air, and the full vacuum is applied for five or ten minutes. This will reduce moisture to about 20 per cent, and induce cracking of the cake. Thereupon the vacuum is cut off and water is applied through the header pipe mentioned. The cake is dislodged in from one to three minutes, and the filtering surface is thoroughly washed. (1,078,994, Nov. 18, 1913.)

**Sterling Silver.**—A new formula for sterling silver is patented by MR. EDWARD D. GLEASON, of New York City. The feature of the formula is the use of boron to give hardness to the resulting alloy, and to remove occluded gases so that castings of the metal will be free from imperfections. The boron is first incorporated with copper, and then this mixture is added to silver. The inventor claims a sterling silver containing from .900 to .925 silver and from .75 to .100 copper and boron. (1,075,642, Oct. 14, 1913.)

### Miscellaneous.

**Production of Phosphoric Acid.**—An improved method of extracting phosphoric acid from natural phosphates consists, according to specifications of patents granted to MR. MAXIMILIAN M. HAFF, of Ottawa, Canada, in subjecting finely pulverized phosphate with clay to electric heat, and recovering the volatilized acid by fixing it with an alkali. The clay used is ordinary blue clay, and it is used in the ratio of 60 parts clay to 100 parts phosphate. The clay and phosphate form a fluid clag under the heat from the electric arc, and the acid is volatilized. No reducing action takes place, and is preferably prevented. (1,076,497-9, Oct. 21, 1913.)

**Metallic Manganese from Ores.**—Mr. Friedrich Heusler, of Dillenburg, Germany, has patented an improved method of extracting manganese from its ores. According to former methods of production, manganese ores were fluxed with lime and with reducing agents such as soot, oil or the like, and heated in a graphite crucible. The yield of manganese is low. The inventor has found that he can obtain a yield within 90 per cent of the theoretical by first calcining a part of the ore, thereby increasing the relative proportion of manganese, and then mixing some of the calcined ore with crude ore, fluxing and reducing as before. The proportions may be varied, but preferably are not below 20 per cent for the crude ore and not above 80 per cent for the calcined product. (1,078,199, Nov. 11, 1913.)

**Solder for Aluminium.**—A formula for aluminium solder, patented by Mr. Charles Willmott, of Smethwick, England, consists of a mixture of 86 per cent tin and 14 per cent bismuth.

**Production of Alkali Metals.**—The decomposition of alkali cyanides for the production of sodium and potassium is patented by Mr. John E. Bucher, of Coventry, R. I. The inventor has discovered that if cyanides of sodium and potassium be heated with iron, or distilled through or in contact with incandescent iron, the cyanides are decomposed, yielding alkali metal and nitrogen. The carbon combines with the iron. (1,079,974, Dec. 2, 1913.)

**Radiothorium.**—Thorium minerals contain a radioactive substance, just as uranium minerals contain radium. In the process of manufacturing Welsbach mantels, a by-product known as meso-thorium is obtained. From this material a radioactive substance can be developed, known as radiothorium. Mr. Lise Meitner, of Berlin, Germany, has patented an electrolytic process of producing radiothorium, consisting in the electrolysis of an acid solution resulting from the extraction of residues from the preparation of mesothorium. Radiothorium separates at the cathode in a relatively pure state. (1,076,141, Oct. 21, 1913.)

**Recovery of Dust from Cement Kilns.**—The dust escaping from cement kilns constitutes a loss of cement-making material, and is undesirable from many other points of view. The difficulty of collecting this dust arises from the high temperature of the gases, thereby eliminating the possible use of bags, as in smelter practice. Washers and the like introduce complications in the draft through the kilns, and have been unsatisfactory. Messrs. Rolla C. Carpenter, of Ithaca, N. N., and Thomas J. Fleming, of Los Angeles, Cal., have patented a process of producing draft in kilns and separating the dust from the waste gases. The dust collecting means consists of houses or structures composed of material having a high rate of heat conductivity and a large radiating surface. In these structures are hung numerous vertical wires or rods, forming a grill to intercept the dust particles. When the dust-laden gases are introduced into the structure, their velocity is greatly decreased, and the solid particles settle out by gravity. This general method has been used in smelting works with great advantage. In order not to interfere with the draft in the kilns, fans are placed between the kilns and the dust-houses. (1,078,254, Nov. 11, 1913.)

---

**Transvaal Gold Production.**—The number of companies reporting to the Transvaal Chamber of Mines in July, 1913, was 62. The quantity of ore milled during that period was 1,913,327 tons. There were 10,015 stamps in operation, with an average duty of 8.54 tons per 24 hours. Tube mills in commission numbered 287. The yield for the month was 655,389 fine ounces gold. The report shows the steadily increasing stamp duty due to the greater number of tube mills used.

## Oxy-Acetylene Welding and Cutting

In connection with the recent New York convention of the American Society of Mechanical Engineers, the Davis-Bournonville Company gave on the afternoon of Dec. 4, to a large number of members of the society, a very interesting series of demonstrations and exhibitions illustrating the development in the oxy-acetylene and oxy-hydrogen processes of welding and cutting metals.

The program included demonstrations of acetylene generation, oxygen generation, welding and cutting torches, cutting steel risers and cutting rivet heads, welding boiler plates and tubes, cast-iron molding, aluminium, brass and copper welding.

A barrel welding machine was exhibited which attracted considerable attention, as did also the emergency equipment. The latter is a small complete outfit, handled easily by two men. The outfit is particularly useful in fire department work, train wrecks, etc. Six cuts were made through bars of iron about 1 in. square in less than two minutes. Among other features was the cutting of a piece of armor plate 16 in. thick with the oxy-hydrogen radiograph.

---

## Laboratory Mill

We have received from Ernst Grunbach & Sohn in Freiberg, Saxony, Germany, a prospectus of a laboratory mill developed by this firm in conjunction with Dr. Th. Koerner.

As shown in the adjoining illustration, the frame of the mill proper is a cast-iron ring closed on both sides by circular plates, one of which is removable for the sake of inspection. The inner periphery of the ring is provided in its upper part with ribs, while a removable screen is placed at the bottom.

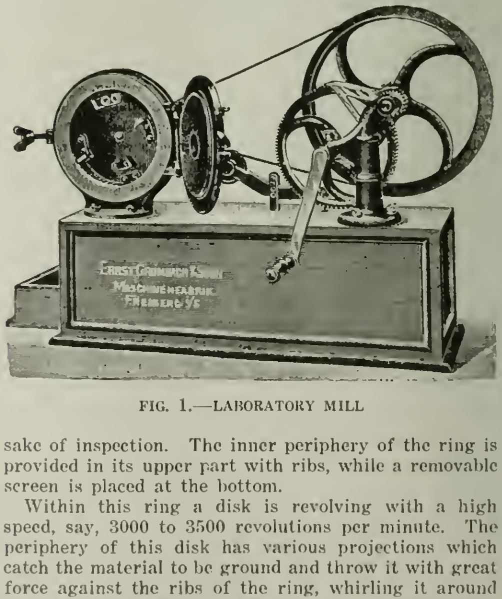

FIG. 1.—LABORATORY MILL

Within this ring a disk is revolving with a high speed, say, 3000 to 3500 revolutions per minute. The periphery of this disk has various projections which catch the material to be ground and throw it with great force against the ribs of the ring, whirling it around until it is disintegrated sufficiently to drop the screen in the bottom.

For cleaning, the mill is opened as shown in the illustrations and the revolving disk is taken out.

An essential element of satisfactory operation is a sufficiently high speed. This is most conveniently obtained by driving the mill with an electric motor.

---

The **Bridgeport Testing Laboratories** announce the removal of their office and industrial chemical laboratory to 388 John Street.

## A New Electrolytic Process for the Production of Flat Perforated Copper Tubing for Radiators

The Electrolytic Products Company of New Jersey, manufacturers of automobiles and house radiators, condensers, tubing, etc., at 75 Clinton Street, Newark, N. J., have just put on the market articles made up of hollow perforated copper tubing produced by a novel and decidedly interesting electrolytic process of their manager, Mr. F. A. Feldkamp. (U. S. Patents 1,055,324, March 11, 1913, and 1,071,036 and 1,071,037, of August 26, 1913.)

Fig. 1 shows an automobile radiator made up of such flat perforated copper tubing and Fig. 2 shows samples of this tubing. The structure of this tubing will be best understood if we first describe merely the chief steps in its manufacture.

A flat lead strip, say of ⅛ in. thickness and perforated at intervals with ¼ in. holes staggered with reference to each other, is electroplated with copper, and the strip is then cut into suitable lengths. These are heated above the melting point of lead; the lead core is thereby melted out. What remains back is the copper plating in form of a light copper tubing of an internal contour corresponding to the original perforated lead strip.

Tubing of this structure is shown in Fig. 2. It is a flat, hollow tubing, the distance between the two parallel flat surfaces being equal to the thickness of the former lead strip (⅛ in.). Where there were the holes in the lead strip, there are now little copper cylinders (diameter ¼ in.) holding the two flat sides of the copper tubing together. This method of construction greatly strengthens the tube against internal or external pressure.

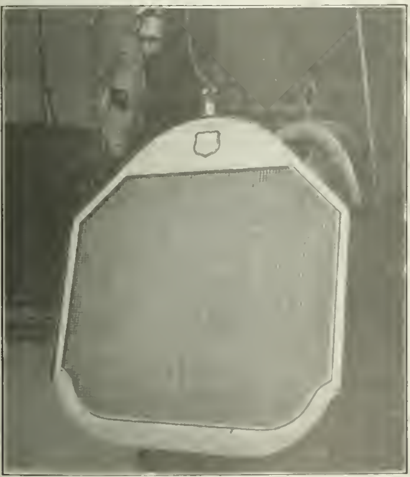

FIG. 1.—AUTOMOBILE RADIATOR

The thickness of the copper walls of the tubing can, of course, be easily adjusted by extending or reducing the time of the electroplating operation. Tubes with walls 0.006 in. thick easily sustain a pressure of 15 lb. per square inch.

As far as the lead is concerned, this is used over and over again, and it may simply be stated that in practice no difficulty whatsoever has been experienced in removing the molten lead out of the copper plate structure. For this reason the process may be called the "plomb-perdu" process.

The chief interest of the process lies in the electroplating operation. This has been made continuous and automatic, the lead passing in form of a long strip through the plating bath. The time during which it is in the bath (or, what is the same, the speed with which the strip is passed through the bath) is so adjusted that a deposit of the desired thickness is obtained.

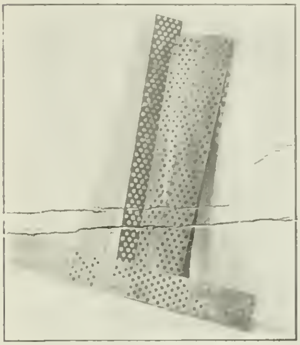

FIG. 2.—HOLLOW PERFORATED COPPER TUBING FOR RADIATOR

The plating bath has a length of 25 ft. One inch of tubing intended for automobile radiators leaves the bath every minute. For thinner tubing, such as used in aeroplane construction, 2 in. of tubing leave the bath every minute.

The chief striking feature of the process is in the anodes. These are in form of wires. The lead strip passes in vertical position and in horizontal direction through the plating bath. On each side of the lead strip there are a number of copper wires above each other, forming the anodes; they also pass in horizontal direction through the plating bath so that they enter the bath with a certain thickness and leave it with a smaller thickness. The wire strands travel through the electrolyte in the same direction of the band from one end of the bath to the other end and then back again.

The arrangement of the several wires is such that at the place of the heavy in-passing wires, there will also be thin out-passing wires. At any point across the series of moving wires within the electroplating tank, the reduction of the wires is such that the sum total of the cross-sectional areas of all the wires always remains the same. Thereby an absolutely uniform deposit from the wire anodes constantly moving through the electrolyte and out again is obtained.

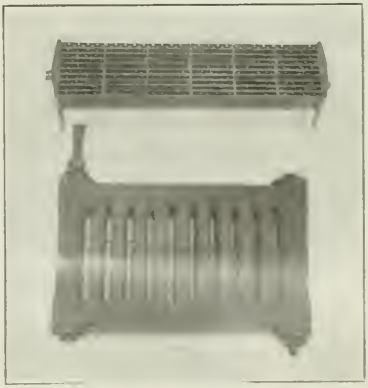

FIG. 3.—COPPER RADIATOR AND IRON RADIATOR FOR HOUSE HEATING

But the use of wire anodes has another important advantage. In the usual electroplating process there is always a loss of anodes in the form of scrap. This often amounts to 50 per cent of the weight of anodes. With this wire anode arrangement not only no anode scrap is produced, but the relative value of the wire is even increased, because thin drawn copper wire is relatively more expensive than thick wire.

The practice of the company is to use wire of No. 8 B. & S. gauge as in-passing wire and let it leave the plating tank as No. 20 B. & S.

Tests of radiators made of this hollow perforated tubing show that they can be built to stand abuse and vibration on automobiles. As to the use of such radiators for ordinary house heating, their very compact form and light weight is a decisive advantage. Fig. 3 shows, for the sake of comparison, a copper radiator of this type and an ordinary iron radiation for house heating. The radiating surface of the copper radiator is 7.52 sq. ft., that of the iron radiator is 7 sq. ft., so that both are about the same. But the weight of the copper radiator is only 3 lb. 6 oz., that of the iron radiator is 48 lb.

Tests of condensers made of this hollow perforated tubing have shown that it is possible to build a condenser that will operate with 8.5 lb. of water per pound of steam, while usually 13 lb. of water per pound of steam is considered excellent and 20 not uncommon.

The manufacturers estimate that they can build a 100-hp condenser exclusive of air pump weighing 30 lb. for the condenser and probably not more than 100 lb. for the containing tank at a greatly reduced cost in comparison with usual constructions.

This tubing may also be used in the arts pertaining to apparatus and devices for electrical, chemical and electrochemical purposes.

While not embodying anything of a revolutionary character, the process is decidedly pretty in its conception and the details have been carefully worked out.

## Laboratory Vacuum Cleaning

In many chemical laboratories a vacuum pump is available for various uses in connection with blow lamps, sand blast, agitation, testing, etc., and the object of this note is to describe the application of the vacuum pump to vacuum cleaning of the laboratory. This is a simple matter, as all that is required is the ordinary dust-separating tank, suitable lengths of pipe or hose, and the cleaning tools.

Fig. 1 shows an illustration of how a simple separating tank can be constructed. This is made of an ordinary 40-quart milk can which may be easily procured at the expense of a couple of dollars. The cover of this can forms an airtight tank and, therefore, is especially adapted for this work. A round hole is cut in the cover and a pipe connection made as shown in detail in the sketch. The pipe or hose connecting the tank with the cleaning tool is attached at this connection.

The connection from the can to the pump is made at the bottom in the same manner as above. This can is to act as a screen and to prevent the dust and dirt from entering the pump, and it, therefore, becomes necessary to provide a screen in the can to catch the dust and dirt. This is provided for by means of a bag made in suitable shape to set into the can about three-fourths of the way down, and made to rest over the neck of the can in such a manner that the cover will be drawn down over the top, holding it secure. This bag may be made of some suitable material such as canvas, canton flannel or suitable silk bolting cloth, depending on the amount of dust and dirt to be removed. The connection to the pump is made by means of pipe nipple and a union.

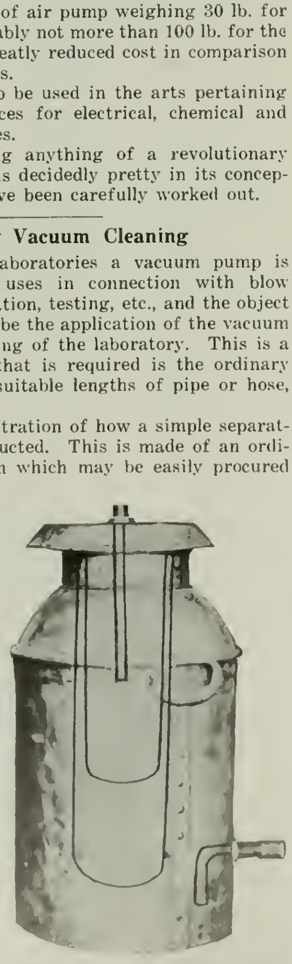

FIG. 1—SEPARATING TANK FOR VACUUM CLEANING

The machine is now ready for operation after attaching a belt to the pump from the motor or a line of shafting.

If the dirt thus taken up contains valuable metals—and this happens often enough in laboratories—they are easily recovered in this manner.

Fig. 2 shows a vacuum pump made by Leiman Brothers, 62 John Street, New York City, specially for laboratory work. These pumps may be procured separately and the balance of the outfit assembled by anyone with any ordinary mechanical ability, or the entire outfits may be secured and the proper connections made. The pipe for blowing can be led from the pump to where the air blast is required and used as stated above for the various purposes in connection with the regular laboratory work.

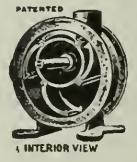

FIG. 2—VACUUM PUMP

## Monel Metal

From Philadelphia comes the report of the consolidation of two of the oldest and most prominent hardware companies into a new corporation to be known as the Supplee-Biddle Hardware Company. The combining firms are the Biddle Hardware Company and the Supplee Hardware Company. The new concern is incorporated for $1,000,000, and will be the largest wholesale hardware distributing house along the Atlantic. Mr. Charles M. Biddle is the chairman of the board.

The corporation will occupy seven buildings, eight stories high and covering about six acres. One entire floor will be given up to Monel metal to the many uses of which the corporation will pay special attention.

As is well known, Monel metal is a "natural alloy" of metal and copper, produced by reduction from the Sudbury nickel-copper ores. It consists approximately of 68 per cent nickel and 30 per cent copper, the balance of 2 per cent being iron and manganese. It has a tensile strength of from 70,000 to 100,000 lb. per sq. in.—greater than bronze and equal to mild steel. It can be easily machined. But perhaps its most characteristic feature is its resistance to corrosion.

Wherever corrosion is a menace, Monel metal rods are proving their superiority over other metals. In pump rods, piston rods, shaftings, valve stems, machine bolts, etc., Monel metal outwears bronze rods by 50 to 100 per cent.

Monel metal pump rods are impervious to superheated steam, do not gather verdigris, and retain a smooth, glassy surface which reduces friction to a minimum and gives greater economy in power.

The Supplee-Biddle Hardware Company cite the experience of a coal-mining concern that placed an order for Monel metal special chute plates some time ago for use in loading gondola cars at their mines. As soon as these chutes were put into use they discovered that the smooth surface of Monel metal obviated the usual choking of coal and that better results and more even loading could be made at a greatly reduced angle of elevation or pitch. Moreover, experience appears to show that coal chutes of Monel metal will outlast steel coal chutes several times over.

To the manufacturer who has lost time and money in a vain attempt to keep acid, salt pickle, tanning or chemical vats and tanks in condition with corrosion eating away his tie rods as fast as they can be replaced, Monel metal tie rods come as a great boon. Monel metal is being used for tie rods of all lengths and descriptions with great success.

Monel metal is also used for valve stems and wire cloth. Screen wire cloth of Monel metal, made by the Biddle Hardware Company, is used for window screening in the city of Colon at the Panama Canal operation. It is the only material the Government has found that will stand the climatic conditions of that territory.

For mines, railway work, chemical plants, sewage disposal plants and engineering operations where ordinary screens are quickly eaten away, Monel metal wire cloth gives splendid service. It has great tensile strength and railway or mine gases do not affect it.

One of the largest developments of the past year has been the successful forging of Monel metal up to 1000 and 2000 lb. Where bronze forgings are now used Monel metal forgings can be substituted. They have the advantage of being non-corrodible and in addition possess all the good qualities of bronze. Owing to the superior strength of Monel metal, lighter forging than bronze can be used unless a large size is essential. The cost of Monel metal forgings will average no more than bronze forgings, and in many cases the cost will be less.

Castings of Monel metal for many purposes have been made for some time, and the ability to make forgings of this metal is of great interest to the manufacturing world. For example, valve rings and seat disks and seat rings of castings are at the present time in extensive use. The Supplee-Biddle Hardware Company is now able to make forgings of disks and seat rings and also valve spindles by this method. In fact, many forgings of steel or bronze can now be duplicated in Monel metal.

Through the use of Monel metal corrugated gaskets the joint can be made as tight and as permanent as any other part of the line.

For use in exposed places where strength is essential and both flexibility and rust-resisting qualities are necessary, Monel metal ropes will give the maximum service and satisfaction.

## Personal

Mr. **Luther B. Eames** has been appointed superintendent of the mill of the Goldfield Consolidated Mines Company, Goldfield, Nevada, and has assumed the duties of his position.

Mr. **H. N. Spicer** was married on November 17, 1913, to Mrs. Laura M. Stoiber. Mr. Spicer is in charge of the New York office of the Dorr Cyanide Machinery Company, and is residing at 12 Fifth Avenue, New York City.

Mr. **H. R. Conklin**, manager for the Lluvia de Oro Mining Company, Lluvia de Oro, Chihuahua, Mexico, was in Denver recently. He is spending some time in the States pending the settlement of troubles in Mexico, which have necessitated closing the property.

Mr. **B. B. Thayer**, president of the Anaconda Copper Mining Company, has been nominated for the presidency of the American Institute of Mining Engineers.

Mr. **Herbert Haas**, of San Francisco, has been appointed metallurgical engineer to the United States Bureau of Mines.

Mr. **C. C. Ferguson**, formerly with the Oliver Iron Mining Company, has been appointed consulting engineer to the Iron Mountain mine on the Cuyuna Range, Minnesota.

Mr. **Robert C. Sticht**, general manager for the Mount Lyell Mining and Railway Company, Tasmania, expects to make a tour of the world. He is expected to leave Australia this month.

Prof. **Robert H. Richards**, of Boston, was a witness in the recent litigation proceedings between the owners of Wilfley and Deister table patents, held at Indianapolis. Mr. **A. R. Wilfley** also was in attendance.

Mr. **Sidney J. Jennings**, vice-president in charge of exploration and mine investment for the United States Smelting, Refining and Mining Company, recently inspected the companies' Utah properties.

Mr. **George F. Waddell** has resigned his position as superintendent of the concentrator of the Steptoe Valley Smelting and Mining Company, McGill, Nevada, to become general manager for the Ohio Copper Company, Bingham and Lark, Utah.

Prof. **G. A. Roush**, of Lehigh University, has been appointed editor of *Mineral Industry*.

Mr. **Richard K. Meade**, consulting chemical, mechanical and industrial engineer, 202 N. Calvert Street, Baltimore, Md., has been retained by the Louisville Cement Co., to prepare plans for their new hydrated lime plant, at Mill Town, Ind. This plant will have a capacity of 60 tons of hydrate per day and be equipped throughout with the most approved appliances for the manufacture of hydrated lime. The plant will be located alongside of their new gas fired kilns on the opposite side of the river from their present hydrated lime plant.

Mr. **John Bellamy Taylor**, formerly with the General Electric Company, has opened offices as consulting electrical engineer at 23 Lowell Road, Schenectady, N. Y., and 100 Broadway, New York.

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

### REFINING METALS (*Continued*).

589,251, Aug. 31, 1897, John Oliver Surtees Elmore, of Kapurthala, India.

Relates to the refining of metals by electrolysis, and consists of a plurality of superimposed horizontal cells made by assembling a large cathode sheet, a wood frame resting on its edges, an anode of impure metal within the frame resting on the cathode, another cathode sheet, another frame and anode, etc., until as many as are wanted have been built up. The cathode sheets are perforated at one end within the frame, the perforations alternated in successive sheets. The assembled cells are suitably bolted together to prevent leakage. Electrolyte flows through the cells in a zigzag course and out of the bottom; it may be filtered when desired; it then flows into a "rocking trough" which empties first into one side, then into the other, of a large tank, and thereby serves to mix it; from the tank it is pumped to the top of the cells; the rocking-trough further serves to prevent a short-circuit. The current dissolves the anode and deposits the metal on the lower side of the cathode sheet above, the anode and cathode sheet constituting secondary electrodes.

589,252, Aug. 31, 1897, John Oliver Surtees Elmore, of Kapurthala, India.

Relates to the refining of metals, and consists of an apparatus constructed on the principle of that in his prior patent 589,251, except that the electrodes are vertical instead of horizontal; thereby forming vertical cells. The anode constitutes a secondary electrode, the electrolyte passing through in a zigzag course. The electrolyte passing out of the cell empties into a "rocking trough" as described in his prior patent.

592,097, Oct. 19, 1897, Bernard Moebius and Gustav Nebel, of New York, N. Y.; said Nebel assignor to said Moebius.

Relates to improvements in apparatus for carrying out the process of electrolytic separation of silver described in U. S. patent 532,209, to Bernard Moebius. In said process it was found that the silver deposited tended to adhere to the belt, requiring scraping and resulting in injury to the belt. This tendency to adhere is overcome by continuously oiling the surface of the belt upon which the silver is to be deposited, which oiling efficiently prevents adhesion of the silver to the belt. The silver belt is also used to convey the deposit out of the tank, instead of transferring it to a separate conveying belt within the apparatus, as in the earlier patent.

593,837, Nov. 16, 1897, George E. Dunton, of Boston, Mass.

Relates to apparatus for continually circulating and thoroughly agitating all kinds of liquids, and especially adapted for electrolytic baths. Located within one corner of a tank is a centrifugal pump having an inlet strainer near the lower end of a suction pipe and an outlet pipe leading from the pump casing to the top of the tank on the opposite side at a point below the level of the liquid contained in the tank. The pump draws the heavy solution through the strainer from one corner at the bottom but without disturbing the sediment on the bottom of the tank, and discharges through an outlet on the opposite side near the top, causing the solution to take a circular motion around and between the anodes and cathodes.

614,633, Nov. 22, 1898, Friedrich A. Thum, of Newark, N. J.

Relates to apparatus for refining metals or extracting metals from ores, slimes, scrap metal, etc., the apparatus operating upon the series, or secondary, electrode principle. A series of racks are placed side by side within a tank at the ends of which are the principal anode and cathode. The racks consist of a frame having a set of spaced bars connecting the ends, and dividing the frame vertically into two halves, one of which is a receptacle for a raw-material container, and the other affording space for the electrolyte. The container consists of a box-like structure having a muslin bottom, which is placed in the frame with the muslin against and supported by the spaced bars. The container is now filled with the slimes or scrap metal, or ore, and against this is placed a metal or carbon plate held in grooves in the frame. The assembled frames are placed in the tank of electrolyte, and so connected that the scrap dissolves as anode and deposits upon the side of the metal or carbon plate of the next frame. The scrap, etc., may be replenished as desired through an opening in the frame.

617,526, Jan. 10, 1899, Elisha Emerson, of Buffalo, N. Y.

Relates to refining metals and depositing the metal as a tube, etc. The improvement is in the anode, which consists of supports of lead or other insoluble conductor, shaped so as to be concentric to the tube being deposited, and upon which (the lead supports) are secured the anodes of copper or other metal to be refined. The copper, etc., is in the shape of bars, which are held in lugs upon the lead supports.

617,886, Jan. 17, 1899, Elias A. Smith, of Anaconda, Mont.

Relates to purifying an impure electrolyte resulting from electro-refining crude copper. Such an electrolyte soon becomes so burdened with arsenic and antimony as to be unfit for further use. It is customary to evaporate it until sulphate crystals form, then run the mother liquid to waste. In the present invention, this mother liquid is still further concentrated in shallow lead pans until the iron salts present have crystallized out, and the specific gravity reaches about 55° Be. The liquor is then run out and cooled, a further deposit of copper sulphate crystals are then obtained, and the excess of liquor removed. To this excess liquor is added crystals of calcium or sodium thio-sulphate, which effect the precipitation of the arsenic and antimony and liberate a supply of sulphur dioxide which remains dissolved in the liquor, which is advantageous in the electrolyte by reducing the remaining iron to the ferrous state, and also retarding the oxidation of the arsenic to copper arsenate as the anode dissolves. After the removal of the arsenic, antimony and other precipitates, the electrolyte may be reused.

625,863, May 30, 1899, Emil Wohlwill, of Hamburg, Germany.

Relates to the refining of gold and gold alloys, using an electrolyte of gold chloride and hydrochloric acid. Prefers to use a solution containing 25 to 30 grams of gold per liter, and from 20 to 50 cubic centimeters of hydrochloric acid of specific gravity 1.19 per liter, at a temperature of from 60° to 70° C. Hydrochloric acid is added to replace that lost, and gold chloride is added periodically to keep a constant per cent in solution. The presence of platinum does not interfere; palladium in quantities of 5 drams per liter does not interfere. Silver accumulates on the anode as silver chloride and may be removed mechanically. In the presence of lead sulphuric acid may be added to the electrolyte to form lead sulphate, which should be removed from the anode. Bismuth may form a precipitate of oxychloride in the absence of sufficient acid. An anode 4 millimeters thick will be nearly consumed in twenty-four hours with a current density of 400 amperes per square meter. The deposited gold is pure.

---

## Book Reviews

**Zink und Cadmium, von R. G. Max Liebig.** 16x23 cm., 598 pages (no index), 205 illustrations, 10 plates; price, bound, 32 marks. Leipzig: Otto Spamer.

At last, German technology has a treatise on the metallurgy of zinc. Professor Schnabel handled it well in his "Handbuch der Metallurgie," but a separate, exhaustive treatise was badly needed. Prof. Dr. F. Fischer, of Göttingen, needed this treatise as part of his collection of books on "Chemische Technologie," and asked the works manager, Max Liebig, to write it. The latter had been in zinc works for nearly a lifetime, and having retired found he had the leisure and the materials wherewith to write the book.

The work handles systematically, completely, and clearly every branch of the metallurgy of zinc. Electric zinc furnaces and electrolytically obtained zinc are satisfactorily written up; in fact, throughout the book, the completeness of the treatment is noticeable and commendable. If the very latest practice of zinc works is in some cases omitted, it is simply because the works refuse to allow it to be published. The *rationale* of the condensation of zinc vapor mixed with other gas is correctly explained on the principle of partial vapor tensions, but instead of this being credited to Roitzheim's publication in *Metallurgie*, in 1910, it should be credited to Richards' "Metallurgical Calculations," Part III, published in METALLURGICAL AND CHEMICAL ENGINEERING (often called Electrochemical and Metallurgical Industry), in 1908.

There are now three treatises on the metallurgy of zinc: that in English, by Ingalls is most complete on the side of American practice; that in French, by Lodin, is most complete on the side of Belgian practice; the German work of Liebig is the most comprehensive book of the three, and should be possessed by every one having any particular interest in any branch of the metallurgy of zinc.

## Aesop at Niagara Falls

A Sentimental Eagle and a Greedy Tiger lived on the bank of a great river, full of fish, and on the other side a Wise Beaver gnawed wood and dwelt at peace with his neighbors for a long time. One day, however, the Eagle and the Beaver disputed over the fish they caught, but at last agreed that for a time each should take a certain amount of fish from the river and so there was peace again.

The Tiger who hitherto had contented himself with other food, seeing that the Eagle was not taking all the fish which were his due, said:

"Behold, I also would eat fish."

Thus there arose a fierce fight between the Eagle and the Tiger; but the Beaver gnawed wood and said nothing.

After a time the Beaver said to himself:

"My foolish neighbors are busy fighting about the fish of which there is abundance in the river for all. My agreement with the Eagle is at an end, why should I not help myself?"

Whereupon, while the Sentimental Eagle and the Greedy Tiger fought, the Wise Beaver fell to catching all the fish he wanted.

*The crown of the wise is their riches:*
*but the foolishness of fools is folly.*

## Keeping Posted

Another chapter has been written on the subject of volatilizing metals as chlorides, which of itself might not excite special comment were it not for the fact that it is almost identical with a similar chapter written ten years ago. There is no thought of charging plagiarism on the part of the second engineer, for in these days of wide publicity in technical matters it would be absurdly foolish to present another man's work as one's own, even after the lapse of a decade. The wonder is that the later investigator carried his work so far without making a search in the literature to see whether his ideas had been anticipated.

About fifteen years ago Messrs. Pohle and Croasdale observed the volatility of metallic chlorides, and as the result of laboratory experiments were encouraged to try the process on a larger scale. Within the next few years they erected a plant, tested many ores, acquired a vast amount of experience and accumulated many data. In 1903 Mr. Croasdale published an article on the subject, and presumably the metallurgical world was properly advised of the status of volatilization as a process for treating ores. Considering the time and money spent in experimentation, the results published by Mr. Croasdale represented the extent of our knowledge on the subject at that time.

Last year Mr. Ben Howe announced from Australia that he had discovered a new process which was going to be of great advantage in the treatment of ores that were refractory to known processes. His work resembled that of Pohle and Croasdale in almost every respect. The apparatus employed for volatilization and condensation, the degree of success attained and the cause for ultimate failure were similar to those of the earlier investigators. And finally, Mr. Howe left the process exactly where American metallurgists had left it ten years before, having spent a great amount of money in duplicating their work, and failing to condense or collect his products, just as they had.

The Australian work was an economic waste of time and money because it demonstrated only known facts.

The moral is plain: before a metallurgist pursues too far an idea that is new to him, let him consult the records which it is one of the functions of a technical journal to preserve. A literary research should precede elaborate experiment. If Mr. Howe had known of Croasdale's work, he might have been discouraged from trying the process or would have tried to improve on it. Had he elected the latter procedure he would have had an excellent starting point. It pays to keep posted.

## The Power Problem of Electrochemistry

The power cost is usually a very considerable item in the cost sheet of electrochemical processes—so much so that this consideration has influenced to a large extent the geographical location of electrochemical industries. The hydro-electrochemical plants of Niagara Falls and Norway are typical examples. But it would be wholly wrong to conclude that electrochemistry must rely on water-power. Water, steam, gas, and even oil, all have their possibilities, according to the requirements of the case and the location. For the case of a large electrolytic copper refinery the subject is admirably treated in the papers of Messrs. Addicks, Longwell and Newbury, reported elsewhere in this issue. But the power problem in electrochemistry is a much broader subject and it is for this reason that this broad general subject has been chosen for a symposium at the general meeting of the American Electrochemical Society, to be held in New York City from April 16 to 18. This should be an opportunity for a lively discussion.

## Steel Costs and Selling Prices

The more optimistic are now insistent that a new era has dawned in the sale of steel products. The selling and operating departments are actually to work in harmony. The sales department is expected to abandon its old policy of advancing prices by getting under them and instead to conduct its sales of products with reference to the cost of producing them. In the one case the general manager of sales consults the cost sheet furnished by the operating department. In the other case he consults the treasurer with reference to the possibility of floating more paper.

The operating man has always felt hurt that while he labors hard and incessantly to save a dime per ton in the cost of producing steel the sales agent carelessly tosses away a dollar to get an order away from a competitor who scarcely needs such incentive to get back at sales agent No. 1 on the next inquiry that comes into the market. Of course, the sales agent's excuse is that a dime saved by improved manufacturing methods is permanent, applying on an indefinite number of tons, whereas the cut price is applicable only to the definite tonnage under negotiation. In practice, however, sales contracts for steel have been virtually guaranteed against decline, and thus the effects of a single cut have often proved far-reaching.

A natural law which is unfortunate from the viewpoint of selling methods in the past is that as the employment of a manufacturing plant increases the unit cost of production decreases. If a plant can produce steel at a cost of $30 a ton when operating at 60 per cent of capacity, and at $29 a ton when operating at 70 per cent, then it requires little computation to show that if the 60 per cent product has been sold at $30 it is theoretically possible to sell another 10 per cent at only $23 a ton and yet have the cost of the entire product equal to the average selling price. If the 10 per cent can be sold at $25 instead of $23 there is apparently an added profit to the mill in making the sale. In a declining market the trick would not work, for the cut price sale would endanger the previous sales made at the higher price, but in an advancing market there is a strong incentive to ignore the advances until full operation is reached.

The greatest friction between the sales and operating departments has come in periods of slack operation, when the sales department cuts prices to "meet the market" and calls upon the operating department to reduce its costs, at the very time when it is wrestling with the impossible problem of preventing the cost from actually rising through the reduced rate of operation. In lighter vein some superintendents have been urging the formation of an "operating men's union" collectively to resist the demands of the sales department and hold it to the basis of the operating costs being shown by the plant at the time the price on a given order is to be quoted. Should such a union succeed, we might have the interesting market spectacle of prices advancing as mills run out of orders and declining as they approach full operation.

Seriously, however, there is need of greater co-operation between the sales organization and the operating organization, and we hope the tendency towards such greater co-operation will grow. If generally practiced it will necessarily inure to the benefit of all.

## Custom Cyanide Mills

A recent venture in running a concentrating-cyaniding mill on a custom basis, in a district producing a wide variety of ores in comparatively small lots, calls attention to difficulties that may be encountered under such conditions. From a mechanical point of view no serious obstacles appear, for the different departments of the mill, such as concentrating, agitating, thickening, leaching or filtering, can be designed to meet the extreme conditions that may arise. Thus the thickening capacity, for example, can be based on the requirements of the ore yielding the slime most difficult to handle; and so on through the other departments. At times this extreme capacity will not be needed, but it is available when required.

Considered from the chemical point of view, however, the difficulties begin to multiply. Unless an elaborate bedding system is provided, with a regular supply of different ores to make the bed, there will be no uniformity in the mill feed. A fifty-ton lot of sulphide ore full of acid or other cyanide may be followed by one requiring little or no protective alkali; and these in turn may be followed by two lots, one of which requires a two-pound cyanide solution while the other will yield its metal only to a five-pound solution. Some lots may require long periods of agitation, while from others the bulk of the precious metals may be dissolved before the agitator is reached. The slime from some ores may have a high settling rate, and thicken to a low-moisture content in decantation, whereas other slime may require filtration for economic treatment. All of these features make it difficult, if not impossible, to obtain uniform milling conditions.

The commercial side of the proposition also offers some obstacles. The schedule of rates must apply to all of the ores offered, whether they are desirable or otherwise; and a nice adjustment is required to have these rates high enough to protect the operator in handling the least desirable ores, and at the same time low enough to attract the ores that are easily treated and from which the most profit can be derived. If other competitive means of ore treatment are at hand, the rate question becomes more troublesome, for the most desirable ores may be diverted to competing buyers who can offer better rates. This will result in surfeiting our custom mill with the most refractory ores from which little profit is to be made.

The conditions described are probably extreme, but are none the less real. They call for the most painstaking preliminary examination before the mill is built, and the best engineering and business skill afterwards.

## The Government's Trust Program

Time has been good to the Washington administration in the matter of the great trust program. Not until now has it been brought squarely to face the duty of developing and enacting a program. Meanwhile the thought of the country has largely crystallized, the trusts, or the "malefactors of great wealth" or whoever they are, have become relatively tractable, and through the training practiced in the tariff and currency legislation the parliamentary body which our last Democratic president referred to as "having on his hands," the present executive could, if he were not far too discreet, refer to as having in his hands.

Viewed with reference to the turmoil and confusion which has raged about the "trust question" the dominant note of President Wilson's address to Congress is not the peace between government and business upon which the daily press has harped, for that we had a right to expect; it is that the problem is to be attacked, not from the viewpoint of history, of what has occurred, of how the so-called "trusts" were put together, but from the viewpoint of what exists, what is private monopoly and what is not, and what is the conduct of great business organizations. It is being more and more frequently said nowadays that the Sherman law is better understood, is almost perfectly understood, but no understanding of that law can prevent the courts, in applying it in specific instances, to look largely to the method of formation of a "trust" thus tending to belittle the cogency of its present position and prospects. The talk at one time ran largely to the question whether an egg could be unscrambled, though some apparently wanted to end the uncertainty by eating it up. President Wilson's message does not run along such lines; it is eminently more practical in directing attention to conserving that which is to-day good, and destroying only that which is to-day bad.

The saneness and reasonableness of the administration's position may possibly be brought out well by the use of a little imagination. Let us conceive a man who can study things only by their genesis and see what a picture he might draw. In the decade of the nineties industry was full of secret agreements, "gentlemen's" agreements, associations, pools, all occasionally successful and all more or less unsuccessful at one time or another. Then came the promoter with Wall Street for the flotation of the securities he would create by buying out competitors, scrambling them, so to speak, and thus conducting the greatest of all conspiracies in restraint of trade, and obviously under the ban of the Sherman law, for years ago the court decided, in a Standard Oil case, that admitting that the separate entities brought together under a holding company had not previously been competitive, yet the formation of the holding company made the control more efficient and more easily administered, and was therefore illegal, even though there had been no competition which could directly be killed. A most lurid picture of what occurred years ago might easily have been drawn, and the viewpoint established of taking the genesis, not the present position and conduct of "big business" as the basis from which the trust problem should be attacked.

The president's message is not about a trust problem, but about a monopoly problem. It refers to what exists, and if it represents, as claimed, the crystallization of public sentiment, then the dissolution suits now in progress under the Sherman law have been an anachronism for some time past.

There lies no menace in the fact that many men will question the new freedom which the administration's program is claimed to promise, on the ground that there is no particular lack of freedom at present. Let the work be prosecuted to a finish. Those who criticise on the ground that there is little good for it to do can hardly at the same time insist that it will do harm. All admit that the removal of uncertainty is of prime importance, and that is clearly promised.

# Readers' Views and Comments

## Relative Thermal Conductivity of Silica and Clay Brick

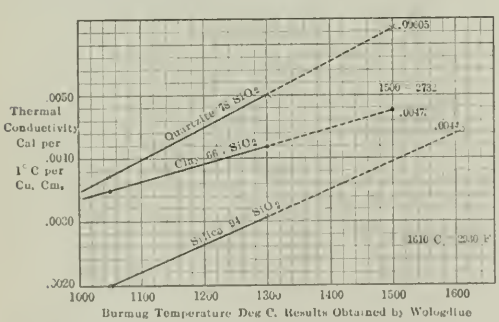
*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Reference has been made in The Metallurgical and Chemical Engineering and other publications during the past year to the heat conducting power of silica brick as compared to clay brick. In practically all cases it has been stated that silica bricks are less perfect conductors than clay bricks.

In the majority of cases this comparison has apparently been taken unquestioned from tests made by Wologdine and published in *Revue de Metallurgie*, June, 1909, and abstracted in Metallurgical and Chemical Engineering of September, 1909. In this paper the following comparison appears:

| Material | Approx. Analysis | Burning Temp., Deg. C. | Conductivity Cal. per 1° C. Diff. per Cu. Cm. |
|---|---|---|---|
| Clay brick .... | 78% $SiO_2$ 18$Al_2O_3$ | 1050 | .0037 |
| | 3.3$Fe_2O_3$.5 CaO | 1300 | .0050 |
| Clay brick .... | 66% $SiO_2$ 29$Al_2O_3$ | 1050 | .0035 |
| | 4 $Fe_2O_3$ .5 CaO | 1300 | .0042 |
| Silica brick ... | 94% $SiO_2$ 1% $Al_2O_3$ | 1050 | .0020 |
| | 2% $Fe_2O_3$.2% CaO | 1300 | .0031 |

These results are shown in the accompanying figure and the curves have been extended to the usual burning temperatures of the three materials. It will be observed that the conductivity of the silica brick burned at about 1600° C. is greater than that for clay as obtained by Wologdine, though somewhat less than the clay results at the usual burning temperature.



THERMAL CONDUCTIVITY OF CLAY BRICK AND SILICA BRICK AS FUNCTION OF BURNING TEMPERATURE

These results in themselves appear somewhat discordant, as it would be expected that the conductivity would vary at least in some regular way with the silica content.

While questioned, these figures are used by Havard in "Refractories and Furnaces" and by Hering in "Flow of Heat Through Bodies" in Metallurgical and Chemical Engineering, December, 1911. In numerous other places these tests appear to have formed the basis for a comparison of the value of these two materials either as heat conductors or as heat insulators. (Compare Randolph "The Conduction of Heat," *General Electric Review*, 1913; Tone "Carborundum Refractories," Metallurgical and Chemical Engineering, October, 1913.)

No doubt these data are correct comparatively for the materials tested, but the results show that the conductivity increases with the temperature of burn and commercial silica brick are burned at a higher temperature than 1300° and at a temperature from 125° to 225° higher than that used for clay brick. Hence, while the results given may be correct for the materials tested, yet they are useless for the comparison of commercial American refractories.

Experience with the use of silica brick as compared with either clay or quartzite brick in by-product coke ovens, gas retorts, checker chambers and many other places has shown that silica bricks are appreciably better conductors than the other two materials. One set of published data shows this. FitzGerald in "Experiments in Heat Insulation" (Metallurgical and Chemical Engineering, May, 1912) shows that 550 watts will maintain a temperature of 660° C. within a small test furnace built of clay brick, while 730 watts are required when silica brick are used.

A carefully conducted series of tests which would give a fair comparison between the refractories in regular use in America would be of value. It is possible that some such data may be available in the files of some of the refractory manufacturers which could be published and would be of value to users of these materials.

S. M. Marshall.

## The Induction Furnace for Steel Melting and Refining

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In your issue of October, 1913, some "Induction Furnace Notes" were given by Mr. Joh. Härdén. In these notes he stated the efficiency of a 2-ton furnace to be 63.8 per cent. In your December issue, however, he corrected this to be 67.1 per cent, assuming that in the first calculation he had made a mistake by using 636 instead of 606 units as the average consumption of electric energy during a run of 606 hours. On the left side of page 561 the time is, however, stated to be 606 hours and the amount of average energy used during said 606 hours to be 636 units. These values appear to be right and Mr. Härdén has probably got the figures mixed up in some way in his latter notes.

The efficiency is more likely to be only 63.8 per cent for a 2-ton furnace as the total efficiency of the 10-ton induction furnaces at the Krupp works is not more than 72 per cent, according to the statement in an advertisement on page 48 of the issue of January, 1913, of your paper. The difference in efficiency of a 2-ton and a 10-ton furnace should certainly be more than some 5 per cent, and this makes it probable that the lower value is the right one for the 2-ton unit. It would be interesting if Mr. Härdén would kindly explain more clearly why the efficiency is not 63.8 per cent as originally was stated.

The opinions about the merits of the induction furnace seem to be rather diverging among metallurgical engineers. In the issue of your journal of November, 1911, Mr. Joh. Härdén makes the statement that "it is well known that very little refining as regards sulphur and phosphorus can be effected in the induction furnace . . . " and proceeds to give some very good reasons for the alleged deficiency of the induction furnace in this respect. This statement is quite interesting as it emanates from a metallurgical engineer of high standing and closely associated with the induction furnace interests in Great Britain.

Contrary to said opinion are, however, some remarks by Mr. C. H. vom Baur in the January number of your journal for 1912, stating that he witnessed a 10-ton induction furnace refining basic Bessemer metal with phosphorus 0.08 and sulphur 0.09, getting $P$ and $S$ down to 0.008 and sometimes to traces and at the same time achieving a high degree of deoxidation.

There is entirely too much discrepancy between the two statements and this fact is certainly worth a careful consideration when deciding whether to install an induction furnace or a modern arc furnace.

In your issue of November, 1911, page 573, Mr. T. D. Robertson also states that the induction furnaces are difficult to use for refining purposes.

The induction furnaces admittedly possess some beautiful features but also have too many practical drawbacks to become ever general favorites or even to enable them to hold the place they have been occupying in the electrometallurgical industry. It would greatly benefit the development of the electric refining methods if an unprejudiced discussion could be started regarding the real and imaginary merits of all the different systems of electric furnaces now offered to the trade.

IVAR RENNERFELT.

Stockholm, Sweden.

## Hydrometallurgy—Joys of Its Practice, Woes of Its Theory

*To the Editor of Metallurgical and Chemical Engineering*:

Sir:—In reply to Mr. Bleecker's communication in your January issue, I will endeavor to establish my former statement that he is ignorant of the subject of dry chlorination. I shall do this impersonally, and mainly because Mr. Bleecker represents in this instance a type of engineer who presumes to pass opinion on matters of which he has little or no knowledge. Ofttimes, through failure of capital to recognize this kind of incompetency, the development of schemes is either undertaken without warrant or unduly delayed. The opinion of this type of engineer is a menace to any industry, whether he be for or against any particular proposal. The fact very often overlooked is that the absorption of knowledge in any one branch of a profession does not of itself qualify one to pass upon matters in every other branch.

Sour grapes? No! Dry chlorination has suffered from over-indorsement. Some of the most favorable indorsements have been based on conclusions equally as absurd as those assumed by Mr. Bleecker against it. I specifically object to incorrect or unwarranted assumptions, whether they be for or against dry chlorination or any other scheme.

A sub-type of engineer equally as dangerous is he who tries to cover his ignorance by shrug of shoulder or a silly smile. In such a case ignorance is accompanied by cowardice.

It was with no hope of convincing the agnostics or the advocates of other methods of ore treatment that dry chlorination will solve the complex ore problem that I threw down the challenge, but rather to bring out into the open if possible those who have selected a dark alley in which to waylay their victim. Certainly a revised code of ethics is needed in our profession, or a better understanding on the part of a few of the code now existing.

Mr. Bleecker excuses his ignorance on the ground that his knowledge was derived from published articles. This will not stand in view of the fact that on June 28, 1911, Mr. Bleecker was invited by me to accompany a party of engineers on the following day to Georgetown to inspect the plant under construction, receive a detailed statement of the proposed *modus operandi*, and go the limit of honest criticism.

Of the articles referred to by Mr. Bleecker, only that of Mr. Wolf was published with my knowledge, and the statements are correct as far as they go. A more detailed statement at that time was deemed unwise on account of the status of patent applications. The "incorrectness and absurdity" mentioned by Mr. Bleecker result solely from the unwarranted assumptions which he makes in connection with the published statements.

For convenience and brevity in making this reply, I have numbered the paragraphs of Mr. Bleecker's communication from 1 to 39 inclusive, and will refer to them by number. Such other items as I consider worthy of attention, and which are not touched on here, are covered in my article on dry chlorination elsewhere in this issue.

14. Certainly Mr. Bleecker's acknowledgments that the cycle of reactions is complete, the chemistry perfect, and the substitution process faultless are facts in favor of the process. Unless these initial conditions existed it would be folly to propose the scheme.

17. Apparently Mr. Bleecker has never made a test for extraction by dry chlorination. I have yet to find a sulphide ore which would not yield its values to any extent desired by the method referred to. As for the handling of chlorine gas, Mr. Bleecker need go no farther than Niagara Falls to enlighten himself on this subject. Referring to materials of construction, there is no need for unlimited choice of such materials for tanks, agitators, and filter presses. Impregnated wood answers every requirement, and asbestos filter cloths are equally as serviceable for filtering the solutions occurring in this process as canvas is in the filtration of non-corrosive solutions.

25-26-27. I wish to confirm Mr. Wolf's statement as to the recovery of from 14.2 to 14.4 pounds of zinc per horsepower-day. I have, however, been unable to ascertain where Mr. Bleecker gets the figure of 3.5 for voltage, as used in his calculations. This voltage was provided to take care of both internal and external resistance, and might justly have been mentioned as the voltage employed. In other words, a total voltage of 75 on a series of 20 cells would be a factor in determining the *cost of electrolysis*, but certainly should not be involved in determining *cell efficiency* as Mr. Bleecker has applied it. The voltage required for internal resistance of each cell did average 3.1. Therefore the theoretical quantity of zinc deposited per horsepower-day at 3.1 volts is

$$\frac{746 \times 24 \times 1.2}{3.1 \times 453.5} = 15.3 \text{ lb.}$$

The ampere-hour efficiency of the cells is $\frac{14.3}{15.3} =$ 93.4%, which is not unusual in other forms of cells. The watt-hour efficiency is 66.4%, thus

$$\frac{746 \times 24 \times 1.2}{2.2 \times 453.5} = 21.53 \qquad \frac{14.3}{21.53} = 66.4\%$$

Can Mr. Bleecker now figure how much "heat" we derive from "calcium sulphate"?

31. Mr. Bleecker is correct. The entire cost of grinding, chloridizing, "bottling," etc., can be done for $1.86 per ton, including the cost of electric power for these operations.

34. Silica, lime, iron, magnesia or arsenic are not factors. The chlorides of metals not sought are employed to chloridize the metals which it is desired to recover from the ore.

37. I have no knowledge of calcium sulphate causing any difficulty. Its presence in solutions has been observed only from slight deposits in first-stage evaporators, but not in the fused zinc chloride.

Mr. Skinner's communication certainly favors the further development of dry chlorination, if for no other purpose than to handle successfully the finely disseminated ores, in the treatment of which there is no competition. That is just the application for which the process is urged as a starter, although I am convinced of its broader application.

The advocates of mechanical concentration can find little solace in the results reported in your January issue on the concentration of the complex sulphide ores at the Mary Murphy mine. I understand that the treatment of this ore is conducted under the most favorable conditions of expert direction and up-to-date appliances, and yet the results are not all that could be desired. It is just such instances which have discouraged even an attempt to apply mechanical concentration to complex ores. It is about time mechanical concentration was passing through a period of refinement; and even if we have competent metallurgists to usher in this period of improved mechanical methods, we can be equally certain that hydrometallurgists will respond to the demands of their profession.

Dry chlorination has been recognized far more favorably by Mr. Skinner than I had expected, but even to win this favor it has not modified its early claims, although it has been willing, for sake of argument, to have its merits determined by using a factor of 2 on its estimated cost of operation. I can understand how those who are actively engaged in mechanical concentration do not find time to consider seriously the developments in other lines. Many have gone to sleep at the switch from sheer exhaustion in meeting the pressing demands of their own work; others find time to make only superficial examination of the claims of other processes, and consequently fall into error.

Denver, Colo. John L. Malm.

## Chemistry of Salt Water Cement

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—To my article on the "Chemistry of Salt Water Cement," published on pages 26 to 30 of your January issue, I wish to make a few additions so as to make them a part and parcel of my original article.

After the fourth line of the right column of page 27, the following insertion should be made:

"It has been authoritatively stated that the Italians were the first to make use of pozzolana, trass, or tuff—together with the admixture of a larger proportion of cement—for making concrete that was to stand in sea water more impermeable and more resistant; both mechanically and chemically. Since then the practice of thus treating concrete has become very popular in Germany and Holland. In Italy, where pozzolana is so abundant, the practice of using only Portland cement, sand, gravel or stone for sea water concrete was looked upon with suspicion. Though the cost of cement is high in Italy, this feeling of doubt is based upon the dangers of decomposition of cement in sea water unless pozzolana was used.

"The successful use of pozzolana by the Italians and the French is no doubt accounted for by the exceptionally good quality of Mediterranean lime. While lime concrete has been used with marked success in the dock work of England, in her sea structures, that is, where the concrete is exposed to the full force of the waves and pounding action of the seas, it had not proven to be a success.

"The excellent results obtained from using pozzolana concrete in sea water structures are shown by the mole of Nero, at Porto d'Anzio, or of Hadrian, near Bari; structures still in existence, though built 17 centuries ago.

"In explanation of the long life of these two structures, Prof. Luigi Luiggi, the noted Italian Engineer, has said: 'Pozzolana contained a large amount of free gelatinous silica ready to combine with the free lime that unfortunately was always present in Portland cement—even the best. Thus, when Pozzolana was added in mixing Portland cement concrete, there was always present a large excess of silica over this free lime, and the result was a kind of acid mixture, instead of the basic mixture that was the consequence of the free lime in cement. This acid concrete resisted better the decomposition of the sulphate of magnesia of sea water, which acted on the basic mortar of concrete—decomposing it and causing free or inert magnesia to be found and sulphate of lime, which had a tendency to crystallize and expand; the consequence of the expansion being disintegration of the concrete."

The beginning of the fourth paragraph of the right-hand column of page 27 should read as follows:

"As considerable stress has been laid above on the German method of manufacturing cement, and on the Italian use of pozzolana, for sea water concrete * * *"

After the 29th line of the right-hand column of page 29, the following paragraphs should be inserted:

"The usual Italian practice for mass concrete laid in harbor work is:

100 to 200 Kilograms of Portland cement,
1 Part ordinary lime; by volume,
2 Parts Pozzolana,
3 Parts gravel or ballast,
for every cubic meter of concrete.

"In discussing this mixture, Prof. Luigi Luiggi says that such concrete will keep plastic for 6 to 8 hours and allow plenty of time for it to be properly pressed into each and every part of the form without tamping. In other words, the concrete is forced into place by hydrostatic pressure; resulting in a more dense concrete than when a quick setting mixture was used. He states concrete made of the above mixture will not suffer any damage after 12 to 20 hours, even from the wash of the waves and that it gives almost as good results as ordinary concrete laid in the opening for block work, etc.

"A mixture commonly used in Italy for premoulded piles, hollow concrete blocks and floating caissons is:

| | Pile work subject to blows | Floating caissons |
|---|---|---|
| Portland cement | 500 to 600 kg. | 350 to 400 kg |
| Pozzolana | 150 to 200 kg. | 100 to 150 kg |
| Sand | 40 cu. m. | .40 cu. m. |
| Gravel or stone 1 in diameter | 80 cu. m. | .80 cu. m |

For 1.1 cu. meter of concrete.

For 1.1 cu. meter of concrete.

"The excess of cement in the pile mixture in comparison with the ordinary mixture quoted above is on account of the heavy blows the piles are subjected to in driving. In the floating caissons mixture the excess of cement is so very small in relation to cost of the reinforcement, forms, labor, etc., as to be negligible; especially in consideration of the great expense necessary to repair an ordinary structure disintegrated under the heavy lateral blows or of sea action. Or as stated above, the increased resistance to sea action more than compensates for the additional amount of cement; especially for that part above low water.

"While a number of experiments made in Scotland show that a 1-2-4 concrete with a $2\frac{1}{2}$ size stone makes the best kind of concrete for mass sea work, at

Southampton it has been found that far better results are obtained in mass concrete deposited under water by using a stone that will pass through a 1-inch ring.

"(NOTE.—The source of the information upon the Scotland experiments seems to refer to premoulded block work not mass concrete deposited under water as per Southampton reference.)

"A method of improving the quality of cement very often practiced in England in connection with the most important concrete structures standing in sea water is that of 'Aerating of the Cement.' The cement is received on the works in bulk form, put into special bins and then turned over a predetermined number of times at regular intervals before being used. It is said that such a treatment of the cement not only increases its resistant power against sea water, but that the increase in bulk more than compensates for the labor cost of the turning."

Seattle, Washington. HARRISON S. TAFT.

## The Western Metallurgical Field

### Flotation of Lead and Copper Ores

As previously mentioned in this column, many companies over the country are investigating the possibility of treating sulphide ores by oil flotation. Where concentrating mills already are established, the line of investigation has been to test the possibilities of flotation for some of the low-grade mill products, such as middlings or tailings. Some of the lead mining companies in southeast Missouri, in the Flat River district, have recently decided to begin treating slime tailings from the mills by flotation. No statement is given as to the process to be used, except that it will be oil flotation. The mill tailings will have to be thickened from about 50:1 to 4:1 before adding the oil in the flotation machines.

The Consolidated Arizona Smelting Co., of Humboldt, Ariz., also is to adopt flotation for the treatment of a part of its mill product. The present mill contains jigs, tables and vanners. According to Mr. G. M. Colvocoresses, who outlined the proposed plan at a recent meeting of the New York section of the Mining and Metallurgical Society of America, the remodeled plant will continue to make jig and table concentrates. The tailings from these machines will be combined with the fine material from classifiers, and reclassified, the coarse portion being reground to 60-mesh in a Hardinge mill. The resulting fine pulp will be thickened in a Dorr thickener, and treated by flotation. The thickening is considered an important point, as the pulp should go to the flotation plant at a consistency of two or two and a half parts water to one of solids. The exact degree to which grinding will have to be carried is not definitely determined, but practically all the mineral is separated from the gangue at 60-mesh. The problem of dewatering the flotation concentrate is one still confronting the management; further, the roasting of very fine concentrate is likely to introduce greater loss in flue dust.

The recovery by present gravity methods of concentration at Humboldt is given as not more than 65 or 70 per cent. Tests from the flotation plant indicate recoveries ranging from 83 to 96 per cent., but it is not anticipated that a recovery of more than 85 to 90 per cent. will be made on the material treated. The exact kind and amount of oil and acid that will be required are not yet determined, and will be subject to experiment after the plant is in operation. The cost for oil and acid is expected to be from 10 to 20 cents per ton treated.

### Minerals Separation Company's Attitude

At the same meeting of the New York section of the Mining and Metallurgical Society of America, mentioned above, Mr. J. Parke Channing gave voice to some thoughts on the methods of exploiting flotation adopted by the Minerals Separation Company. Many of the same sentiments have been expressed throughout the West, and the feeling prevails that this company makes the terms for adopting its process needlessly onerous. As Mr. Channing has expressed the idea in forcible manner, we quote the following from his remarks, as published in the Society's *Bulletin No. 67*:

"Unfortunately, the Minerals Separation Company has firmly rooted ideas as to the exact manner in which the process shall be applied, which ideas have met with very little favor among American engineers. What the company would like to do is to take your ore, experiment with it, and if it concludes that the ore can be treated, it will build your mill and treat the ore. Now few engineers feel like leaving the erection of a mill treating 3,000 to 10,000 tons a day to the mercy of English engineers who are used to handling small tonnages. As a result, the company has not been able to induce American mines to coöperate with it.

"A second drawback is that the company desires to treat the whole of a given ore by flotation. The process gives a very high recovery of rich mineral, but in such physical condition that it is not easily amenable to the smelting operations which have to follow. This is the method it proposed to the Caucasus Copper Co., of Russia. There, by the present water concentration, they get a 70 per cent. extraction; by flotation experiments they got 95 per cent. The Minerals Separation Company would agree to permit the copper company to use the process only if applied to the entire ore. The copper company wisely refused to do this, realizing that it would be impossible to treat such fine concentrate in McDougall roasters and reverberatory furnaces.

"The Inspiration mine, I understand, agrees to pay a certain royalty based upon the tons of material actually treated by the process. The construction of the mill is left entirely to the engineers of the Inspiration, and in their case the treatment is to be preceded by water concentration. After a portion of the chalcocite is extracted the remainder is treated by flotation. At Miami we have as yet made no experiments with the flotation process, and I do not know exactly how it will work out on our ore. Any flotation system works better on ores containing pyrite or chalcopyrite than on ores containing chalcocite. At the Inspiration, however, when the middlings were crushed to 100-mesh, they made a very satisfactory saving on the chalcocite."

### Smelting in Nevada

With the operation of copper converters which were recently installed at the smelter of the Mason Valley Company, the plant is now completely equipped for the production of blister copper. Converting operations began about the first of this year, and brought to an end the shipments of matte which have been going to the Garfield smelter in Utah since Mason Valley first began to smelt. The new department has ample capacity to handle the matte now produced from both company and custom ores.

Progress is being made by the new Consolidated Coppermines Co., which consolidated a number of mines in the Ely district, including the Giroux. Churn drills are steadily at work prospecting the ground now under this company's control, and a considerable area of new ground has been found ore-bearing. Financial arrangements were recently completed for the erection of a smelting works. A bond issue has been authorized to the extent of $3,500,000 at 7 per cent. interest, payable semi-annually. The location of the new smelter is not definitely settled, although a corps of engineers has surveyed a site at Warm Springs which is known to be favored by the management. In all probability the matter will not be settled until the company knows what attitude the surrounding land owners will take in regard to smelter smoke. The company has asked these people to waive future damage from smelter smoke, and is engaged in now getting their signatures to such an agreement.

### Purchase of Colorado Gold-Dredging Industry

The Tonopah Mining Co., engaged in mining at Tonopah, Nevada, has recently purchased the property and equipment of the gold-dredging companies operating in the vicinity of Breckenridge, Colorado. The transaction includes the dredges of the Reliance Gold Dredging Co., and the Colorado Dredging Co., the machine shops of the Gold Pan, and several thousand acres of land. The Tonopah company has been looking for a new mining property for some time, and has finally made a new venture by embarking in dredge boats in a search for gold. The sale was one of the largest that has been made in Colorado for years, and is said to have involved a million dollars.

### Estimated Budget for Bureau of Mines

The estimate expense for conducting the work of the U. S. Bureau of Mines for the fiscal year ending June 30, 1915, has been approved by Secretary Lane of the department of the interior and forwarded to Congress. No action has been taken at the time of writing, but it is probable that the estimate will be allowed. The proposed division of the appropriation is as follows:

| | |
|---|---|
| General expenses of the bureau | $70,000 |
| Equipment of mine rescue cars and stations | 30,000 |
| Equipment of Pittsburgh testing plant | 10,000 |
| Investigating mine accidents | 347,000 |
| Testing fuels | 135,000 |
| Mineral mining investigations | 120,000 |
| Investigations of petroleum and natural gas | 30,000 |
| Inspection of mines in Alaska | 7,000 |
| Books and publications | 2,000 |
| Lands, leases, etc., for mine rescue cars | 1,000 |
| Total | $752,000 |

This budget provides for an increase over that of the current fiscal year of $90,000, represented by the items of $30,000 for equipment of rescue cars and stations, $10,000 for equipment for Pittsburgh testing plant, $30,000 for investigations in petroleum and natural gas, and a $20,000 increase in the former appropriation for mineral mining. It is understood that part of the appropriation for petroleum and natural gas will revert to mineral mining investigations, on account of the fact that part of the present appropriation for the latter purpose has already been diverted to the former.

As an instance of the need for funds to investigate petroleum and natural gas, the conditions existing in the Cushing field of Oklahoma are cited. The maximum yield of oil in that district has never been over 30,000 barrels per day, and the average value of daily production is probably less than $20,000. Nevertheless the waste of natural gas from drilling and producing wells in this district has been as high as 300,000,000 cubic feet per day, worth about $75,000 at domestic rates, or perhaps $20,000 per day to the producers. It is to study such conditions that the appropriation for oil and gas investigations is asked.

### Labor Situation in Michigan

The deportation of Mr. Moyer, president of the Western Federation of Miners, from Houghton, and his later indictment by a grand jury, are the principal features of the labor strike in Michigan. Federation officials were indicted for conspiracy to restrain laborers from going to work, for restraining imported laborers from working, and depriving laborers of their rights and property. Thirty-nine officials were named in one indictment.

## The Non-Ferrous Metal Market

During the last week in December the non-ferrous metal market showed more activity than had been in evidence for some time, and sales were large at slightly increased prices. But during the first week of the new year the activity disappeared and the markets experienced a general decline.

**Copper.**—Competitive selling has marked the activity in this market to such an extent that consumers have been inclined to hold off on account of the demoralization in prices. Prices for electrolytic have declined daily and the market for Lake is wholly nominal. The latest available quotations are 13.80 to 13.90 cents for electrolytic, with the market weak.

**Tin.**—Considerable business was transacted in the domestic market during the last of December, but with the decline in the London market in the first week of January domestic buying ceased and a low price was established. January tin was quoted at 36¾ cents.

**Lead.**—The leading producer has fixed prices, which showed a slight advance during the holidays, but again declined in January. Independent producers were at first inclined to let the A. S. & R. Co. take the business, but later offered metal liberally. The last quotations are 4.10 cents New York, and about 4 cents St. Louis.

**Spelter.**—This market has been dull with little fluctuation in prices. Sales are not heavy and consumers are buying only for immediate needs. New York quotations are 5.20 to 5.25 cents, with St. Louis at 5.05 to 5.10 cents.

**Other Metals.**—The aluminium market shows a slight improvement, with quotations at 18½ to 19 cents. Antimony is quiet, with fair sales for immediate delivery. Various brands are quoted at from 6 to 7.30 cents. A steady business prevails in quicksilver, with New York prices $38 to $39 per flask of 75 lb., and $38.50 at San Francisco.

## The Iron and Steel Market

The slight improvement in the general tone of the iron and steel market, referred to in last report as occurring in the closing days of December, has developed into a definite and clearly market improvement in the past month. There has as yet been nothing like the spectacular revival which has often characterized the industry's recovery from depression, but there has been a decided improvement in bookings and production, and a slight stiffening in prices, amounting in the case of a few products to definite advances.

Many of the steel mills closed entirely over the holidays, and some of the attendant blast furnaces, to the number of more than a score, were banked. Resumptions occurred at various times in the first fortnight of January and at the close of the month the steel industry is operating at fully 60 per cent of its maximum capacity, while the actual production in the month was between 50 and 55 per cent of capacity. These percentages compare with operation at the rate of about 50 per cent in the fore part of December, and production for the month as a whole little if any over 40 per cent of capacity.

There has been very little long term contract tonnage booked, the mills instead looking for definite orders, with specifications attached. It is possible that the refusal of mills to protect buyers by giving them the usual option or "jug handled" contracts has been largely responsible for the increase in actual specifications, particularly since the lowest prices have been named on definite orders rather than on contracts. At the lowest—the general level being now discernibly above the minimum—prices did not reach the low average of two years ago by about $2 a ton, and this fact is variously explained. The mills have certainly been under as much competitive strain lately as at the former minimum, perhaps under more. Increased cost of production, through the general wage advance of February 1, 1913, is cited as one cause, while another seems to be that the mills have a different philosophy now.

With the low tariff in effect there is less promise than formerly of relatively high prices for any period in the future, and there is therefore less inducement to start a buying movement by naming very low prices and then expecting a prolonged advance in prices to produce a fair average. In many cases it is known that the sales offices are working more closely in harmony with the operating departments and paying more attention to the cost sheets.

### Pig Iron

Buying of pig iron in January was fairly heavy, and was marked by the first definite buying for forward delivery since last midsummer. For months buyers had covered only for immediate requirements, but late in December some of the larger buyers began to adopt the idea that if prices were not definitely advancing, they at least stood much more chance of averaging higher than of averaging lower, during the first six or nine months of the year. Buyers who have covered, however, have not taken tonnages equal to their full normal requirements. Under stress of competition produced by important inquiries prices declined in many markets early in January, but at the close of the month the advancing tendency seems to predominate, and at Buffalo there has been a clear cut advance of 50 cents a ton.

The manufacturers of Bessemer and basic pig iron in the valleys are as a rule holding their output at higher prices than are openly quoted as a market. Quotations stand as follows: No. 2 foundry, f.o.b. Birmingham, $10.50 to $10.75; No. 2X foundry, delivered Philadelphia, $14.75 to $15; No. 2 foundry, f.o.b. furnace, Buffalo, $12.50 to $13; No. 2 foundry, delivered Cleveland, $13.25; No. 2 foundry, f.o.b. Chicago furnace, $13.50 to $14; at valley furnaces (90 cents higher delivered Pittsburgh), Bessemer, $14; basic, $12.50; No. 2 foundry, $13; malleable, $12.75; gray forge, $12.50. Late in December the Carnegie Steel Company appeared as a seller of ferromanganese, which it had previously made only for its own use, and it closed several contracts with consumers for their requirements during the first six months of the year, on the basis of a price to be named each month, the price to be about $2 below the price of imported material. The price for January was fixed at $47, delivered to points near Pittsburgh. In a short time the English and German makers reduced their price from $47 to $45, f.o.b. Baltimore.

### Steel

Late in December a slight further weakening occurred in unfinished steel, chiefly with respect to open-hearth sheet bars, which were offered down to $20, maker's mill, Pittsburgh or Youngstown, the quotation on Bessemer bars remaining at $21, while billets were not generally quoted below $20. After the 15th of the month the Carnegie Steel Company announced its withdrawal from the market as a seller of billets or sheet bars and the tone of the market began to improve, until it became difficult to buy open-hearth bars at the old price.

No clear cut advance, however, has occurred in unfinished steel, except that rods have been advanced from $25 to $26.

### Finished Steel

The trend in unfinished steel prices has been in the upward direction, though there have been few definite advances. Bars, plates and shapes late in December could be done at 1.15 cents, on attractive tonnages for quick shipment, though the open quotation was 1.20 cents, and the concession is now practically withdrawn, except as to bars and plates in Chicago territory. During the last week in the old year and the first week in the new mills booked definite orders for wire nails at $1.50, and then firmed up to a $1.55 basis. Sheets were done freely on the basis of 1.80 cents, but early in January firmed up to 1.85 cents, and on January 22 the leading interest made the somewhat radical advance to a basis of 2 cents, a price which the independents will probably reach early in March.

In all cases the firming up in prices has been due to the receipt of heavier bookings in the form of actual specifications.

Prices named below are f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard section, 1.25c. for Bessemer; 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.20c.

Shapes, 1.20c.

Steel bars, 1.20c., base.

Iron bars, 1.35c., Pittsburgh; 1.22½c., Philadelphia; 1.10c., Chicago.

Wire nails, $1.55 per keg, base; plain wire, 1.35c., base.

Sheets, blue annealed, 10 gage, 1.45c.; black, 28 gage. 1.90c. to 2c.; galvanized, 28 gage, 2.90c. to 3c.; tin mill black, 1.85c. to 1.95c.; painted corrugated, 28 gage, 2.10c. to 2.20c.; galvanized corrugated, 28 gage, 2.95c. to 3.05c.

Merchant steel pipe, ¾ to 3-in., 80 per cent. off list.

Steel boiler tubes, 3½ to 4½-in., 71 per cent. off list. (Revised from 69 per cent. on January 2d.)

Standard railroad spikes, Pittsburgh, 1.50c.; Chicago, 1.50c.

Structural rivets, 1.70c.; boiler rivets, 1.80c.

Cold rolled shafting, 64 per cent. off list.

## A Symposium of Papers on "Undeveloped Elements"

The next meeting of the New York section of the American Electrochemical Society will be held in the Chemists Club Building in the evening of Friday, February 6.

This meeting will be a joint meeting with the New York sections of the American Chemical Society and the Society of Chemical Industry.

The subject of the evening will be "Undeveloped Elements" and the program is as follows:

"Opening up the Field of Unused Elements." By Dr. Charles Baskerville.

"The Present Status of Cobalt." By Dr. H. T. Kalmus.

"The Present Status of Boron." By Dr. E. Weintraub.

"The Present Status of Tungsten." By Dr. R. W. Moore.

By "undeveloped elements" is meant those elements which are available as by-products or otherwise in excess of present demand. Some are dead, such as tellurium; some are comatose, such as selenium and cadmium; some are very limited in their applications, such as bromine.

Discussion will not be limited to the actual papers presented.

It is hoped that an interesting exhibit can be made of products relating to the subject.

## Patent Suit Decision on Manufacture of Chill-Proof Beer

A decision has just been rendered in the patent suit for the manufacture of chill-proof beer in the United States District Court of the Eastern District of New York. The plaintiffs were Max Wallerstein and Leo Wallerstein, suing the S. Liebmann's Sons Brewing Company for infringement of Leo Wallerstein's patents, 995,820 and 995,824.

The decision of the court, written by Judge Van Vechten Veeder, is in favor of the complainants, the patents in issue being held valid and infringed.

The following quotations from the decision seem to be of general interest to chemists:

"The development of the bottling industry brought about a change in the method of consumption of beer. Instead of being served from the keg, or at all events within a short time after leaving the brewery, it was shipped long distances and kept for considerable periods of time. When thus kept, even at ordinary temperatures, beer tends, from a lack of stability, to become hazy and cloudy, and to deposit a sediment. But in this country it is customary to drink bottled beer very cold. This chilling causes brilliant beers or sparkling ales to lose their brilliancy and to become hazy and cloudy. It was soon found that under conditions of long shipment and storage the most carefully brewed beer developed micro-organic growths. To eliminate this brewers adopted the practice of pasteurization; that is, the beer in bottles was subjected to a temperature of from 140 deg. to 150 deg. F. for about half an hour. But while pasteurization prevented the growth of microorganisms, pasteurized beer was found to be particularly sensitive to cold and unstable. There remain in the beer after steaming certain substances of an albuminous nature, which, while invisible at the time of steaming because dissolved, are slowly affected by a number of causes and become less readily soluble, especially at low temperatures, finally causing haziness or sedimentation and thus rendering the beer unsightly and unpresentable.

"The production of stable and chill-proof beer was therefore a problem of vital importance to brewers. The evidence leaves no doubt of the reality of the problem or of the difficulty involved in its solution." . . . .

"The patents in suit produce chill-proof and stable beer by adding to the beer at the proper stage a minute quantity of a proteolytic enzym active in an acid medium. Proteolytic enzyms are divided into classes according to the medium in which they act, that is, whether acid, neutral or alkaline. The patents in suit refer to four proteolytic enzyms active in acid medium: pepsin, an animal enzym obtained from the stomach of pigs; papain, an enzym derived from the pawpaw; bromelin, a vegetable enzym derived from the pineapple, and malt peptase, derived from malt. Enzyms suitable for the purpose described are widely distributed in the vegetable and animal kingdoms, and are readily prepared in concentrated form by known methods.

"The procedure by which proteolytic enzyms active in an acid medium are employed for the purpose of chillproofing and stabilizing beer, is exceedingly simple, and is specifically set forth in the patents in suit: 'According to the present process, there is added to the beer at any suitable stage of the brewing, that is to say at any period subsequent to the cooling of the wort, and usually after the conclusion of the main fermentation, a proportion of proteolytic enzyms active in slightly acid media sufficient to modify the proteids contained in the beer in such manner that they will not be precipitated upon chilling subsequent to pasteurization, the beer being rendered chill-proof in the sense that it is capable of remaining brilliant even when kept upon ice for a considerable time. In practice it has been found advantageous in most cases to add the enzyms to the clarified beer shortly before bottling. During the pasteurization which follows the bottling, the enzyms become active, and those proteids which would cloud the beer when chilled are so modified by the proteolysis that the resulting beer will remain clear and brilliant, being no longer sensitive to cold.' " . . . .

"Since the evidence satisfies me beyond any reasonable doubt that the defendant's beer is made chill-proof and stable by the use of proteolytic enzyms active in acid medium, and that the infringement is a deliberate and flagrant appropriation of Wallerstein's disclosures, attention may be directed at once to the grounds upon which the validity of the patent is attacked.

"The defendant introduced much testimony to show that certain extracts have long been made by compounding pepsin with malt liquor, the latter serving as a carrier for the former. It may be said at the outset that the defendant's testimony with respect to these malt preparations is wholly unsatisfactory. The testimony of the defendant's witness Wyatt was so obviously unbelievable that its counsel stated upon the argument that it would not be relied upon." . . . .

"My conclusion is that the patents in issue are valid and infringed. The complainants may have the usual degree."

## Bitumen and Electric Main Explosions

The British Board of Trade has appointed a committee to investigate the explosions connected with electric mains laid in bitumen. The inquiry is the outcome of an explosion of gas at Hebburn-on-Tyne, several months ago, by which two houses were blown up and two persons were killed, and which was attributed to gas generated from the bitumen in the trough at a bend where a fault in a direct-current vulcanized-bitumen-insulated cable at a moist spot caused a short circuit and consequent destruction of about 6 ft. of cable and the bitumen in which it was laid.

The fault was very close to the house, the gas found its way through loosely constructed foundations into large air spaces under the ground floors, air was supplied by a ventilator inlet facing the fault, and, in some unascertained way the mixture became ignited, with the result stated.

Hitherto considerable divergence of opinion has existed as to the causes of joint-box and similar explosions, and on some occasions very elaborate theories have been advanced. In the case of an explosion in London several years ago certain experts attributed the ignition of the explosive gaseous mixture to the action of water on metallic sodium produced by the electrolysis of sodium salts derived from the surrounding soil; but in this instance the cable was not laid in bitumen and the hydro-carbon gases were said to have been derived from a neighboring gaspipe.

Bitumen is so extensively used both as filling for cable troughs and, when vulcanized, as a dielectric covering for cables that all who are concerned will regard an official inquiry with satisfaction.

## Bureau of Standards Analyzed Brass Samples

The Bureau of Standards, Washington, D. C., is prepared to issue a sheet brass of the following composition, approximately: Sn, 1; Pb, 1; Cu, 70.3; Zn, 27; Fe, 0.3; Ni, 0.5. The fee, payable in advance, is $3 per sample of about 150 grams weight.

# Test of a Vacuum Pan

BY E. W. KERR

The following data were obtained from a test of a vacuum pan in a Louisiana sugar house where white sugar is made direct from the cane. The pan tested was of the calandria type, known as the Stade express vacuum pan.

This type is shown diagrammatically in Figs. 39 and 40 on pages 349 and 350 of the July, 1911, number of METALLURGICAL AND CHEMICAL ENGINEERING. It should be stated, however, that the condenser of the pan tested was a dry condenser and differed materially from the illustration mentioned.

The object of the test was to secure data relative to heat transmission, also steam consumption. The test was, in fact, a history of one strike.

The syrup fed during the test was measured in large storage tanks which were carefully calibrated.

The density of the syrup fed and of the masse-cuite leaving was obtained by means of Brix spindles which had been carefully calibrated.

The weight of condensed steam leaving the pan was measured by means of a Venturi meter, the manometer of which was read every two minutes throughout the test.

The condensed steam was removed from the pan and pumped directly into the boilers by means of an automatic receiver pump.

The receiver being of liberal capacity, the flow of condensed steam from the pan was fairly steady and for this reason the meter readings should be fairly accurate.

The amount of water removed from the syrup in the form of vapor during the boiling process was calculated from the weight of syrup fed and the initial and final density.

One of the items difficult to obtain in determining a heat balance is that of the specific heat of the syrup, also that of the masse-cuite.

In arriving at this quantity it was assumed that the specific heat of the mixture of sugar and water was equal to the sum of the heat in the dry matter plus the heat of the water, degrees Brix, representing the per cent of solid matter.

It will be noticed that the purity of the product was 71.5 per cent, that is, of the total dry matter 71.5 per cent was sugar.

In the specific heat determination it was assumed that all of the solid matter was sugar, which may not be absolutely accurate, though it is probably very nearly so.

The specific heat of sugar was taken to be 0.301.

I hope the results of this test will be found interesting. So far as I know no data of this nature have been published.

The results of the test are given concisely in the table in the right-hand column of this page, together with a heat balance sheet, showing the amounts of heat entering and leaving and the heat lost in radiation and not accounted for.

Louisiana State University and Audubon Sugar School.
Baton Rouge, La.

## Summary of Test

| | | |
|---|---|---|
| 1. | Type of pan | Calandria (Express) |
| 2. | Type of condenser | Counter current jet (Barometric) |
| | DIMENSIONS | |
| 3. | Heating surface, square feet | 750 |
| 4. | Diameter of pan, feet | 13 |
| | PRESSURES | |
| 5. | Pressure of steam to pan calandria, lbs. gage | 28.8 |
| 6. | Vacuum in vapor space, inches of mercury | 23.4 |
| | TEMPERATURES AND DENSITIES | |
| 7. | Temperature* of steam in calandria of pan | 272 |
| 8. | Temperature of steam, condensed | 270 |
| 9. | Temperature in vapor space | 143 |
| 10. | Temperature of entering syrup | 175 |
| 11. | Temperature of masse-cuite leaving | 156.7 |
| 12. | Temperature of injection water entering condenser | 64 |
| 13. | Temperature of injection water leaving condenser | 132 |
| 14. | Density of syrup entering, Brix | 49.4 |
| 15. | Density of masse-cuite leaving, Brix | 94.8 |
| 16. | Purity of syrup fed | 71.5 |
| | TOTAL QUANTITIES | |
| 17. | Duration of test (strike), hours | 6.05 |
| 18. | Volume of syrup fed, gallons | 15,387 |
| 19. | Weight of syrup fed, pounds | 152,932 |
| 20. | Per cent evaporation | 47.89 |
| 21. | Weight of water evaporated from syrup, pounds | 73,139 |
| 22. | Weight of steam condensed, pounds | 93,815 |
| 23. | Weight of cooling water to condenser, pounds | 1,100,010 |
| | HOURLY QUANTITIES | |
| 24. | Syrup fed, per hour, pounds | 25,278 |
| 25. | Water evaporated from syrup per hour, pounds | 12,089 |
| 26. | Steam supplied per hour, pounds | 12,200 |
| | GENERAL QUANTITIES | |
| 27. | Total water evaporated from syrup, per pound of steam supplied | 778 |
| 28. | Total water evaporated per square foot heating surface, per hour | 16.12 |
| 29. | Temperature fall, actual | 115.8 |
| 30. | Coefficient of heat transmission | 166.3 |
| 31. | Cooling water per pound of vapor | 15.04 |

# Electric Iron Smelting at Hardanger in Norway

BY JOH. HÄRDÉN

Mr. G. Oedquist has in an interesting and suggestive paper,[*] read before the Polytechnic Society of Kristiania, Norway, given a comparatively full report of the facts which, according to his mind, have caused electric smelting to give an unfavorable result at Hardanzer, in Norway, as far as the economy goes.

As the paper is evidently written with the view to lay clear such instances as are likely to occur in other places, a résumé of the contents seems justified; a few remarks of the present author's experience on similar lines will be added. The main points of Mr. Oedquist's paper are:

Since the problem of electric smelting of iron ore has the greatest future and importance for such countries as Scandinavia, on account of the tremendous sources of both water power and deposits of high-quality iron ore (which factors are essential for the success of electric smelting), it is well worth while to go into the causes of the unsatisfactory outcome of the trials, so far made at Hardanger. A few comparisons will be made between this plant, where coke was used exclusively, and a few others, where charcoal is used.

The author of the paper in question does not mention the facts that the choice of reducing agent—coke versus charcoal—is an important factor in the whole problem, yet all available data seems to point out that this must be so, at least for the present, and it appears to the present author that the coal question is of at least as much importance as the question of cheap power and good ore.

As far as can be concluded from the various reports, the operation with coke direct in the furnace has essential drawbacks, some of which appear in the report, as will be seen. In the first place, the conductivity of the coke is high, hence a large current density at a lower voltage is likely to be required, and this will in turn increase the electrical losses and cause the plant to be more expensive, with a lower efficiency. This is borne out by the paper, as will be seen. Further coke is always richer in sulphur and, therefore, demands a larger addition of lime, which increases the dead ballast in the furnace, thus lowering the output; this is also mentioned, though in a somewhat different way. True, coke may be obtained with a low percentage of sulphur, but such coke is much more expensive and throws the balance the wrong way.

Against this, charcoal is much more suitable, on account of its lower conductivity, low content of sulphur, and its gas producing properties. But charcoal is expensive, even at its best, and there is likely to be difficulty to obtain a proper supply of charcoal in Norway, especially at places like Hardanger, where the other factors may be more favorable; hence if charcoal were to be used, it must be subjected to import or long freight, but this burden it cannot very well bear on account of its initial price and its bulky mass.

Even in Sweden, where charcoal may be obtained more readily, the question has become "a burning problem." It is reported elsewhere that owing to the large demand for charcoal wood, the manufacturers are gradually forced to make use of younger, quick-growing trees, on which the percentage of bark is rather high. As the bark contains a larger proportion of phosphorus, this obnoxious element is introduced into the otherwise pure ore and tends to lower the quality of the product. One should think that the phosphorus should be eliminated in the charring process, but report says that this is not so, and to remove the bark would mean an increased cost and loss of material.

This, of course, does not apply so much to charcoal made from refuse from saw mills, since the wood is generally barked before putting it through the saw mill; but it is generally assumed that the coal from "natural" wood has a higher value, if made from the right kind of wood.

From this it would seem that the coal question for electric iron smelting is a very important one.

But to recur to the paper under review, it is stated that the conclusions in the report are made from official statements, made by the Electrometallurgical Committee regarding the trials at Hardanger, and may be found in *Teknisk Ugeblad*, 1913, page 192.

Mr. Oedquist concludes that reading through these statements one cannot help arriving at the surmise that everything was relatively well and good, and that the poor results were to be found here to "misadventure" and outside conditions, particularly to the use of unfavorable ores in some cases, bad roasting of the ore, some of the electrical details not being suitable, unfavorable conjunctures and high freights.

Regarding the furnace type, however, and its adaptability for coke, the committee maintains that this has no part in the failure.

Mr. Oedquist in his paper does not agree with the committee on that point, but thinks that on the contrary the type of furnace design and its unsuitability for working with coke has had a great effect upon the results and in a high degree caused the expectations made at the Hardanger works to be a disillusion.

He endeavors to give strength to this claim in his paper and to explain in what way he has arrived at this conclusion.

As regards the unfavorable conjunctures referred to, the author of the paper says, he does not intend to go into this question at large, nor the freight conditions, as it is outside the scope of his issue; he will only mention that these conditions are always subject to changes and must be taken into consideration *a priori*. Especially as the Hardanger works has only taken a part of the whole program laid out in the prospectus. However important these factors may have been, one must look deeper into the matter in order to find the actual reasons for the unsatisfactory results obtained.

Proceeding to do so, the author commences with some scathing remarks regarding the electrical equipment at Hardanger.

The committee says in regard to this that the choice of transformers and regulating arrangements very soon proved to be unsuitable for the purpose. Furthermore, the manner in which the leads were laid out from the secondary to the furnaces, and the way the connections to the electrodes were carried out, caused the system to work under such bad conditions, that only about two-thirds of the power contracted for was available at the furnace. The committee adds:

"As the plant was carefully inspected electrically before taken into use, without any mentioning of these faults, one was led to believe for a long period that the bad results were due to faulty operation of the furnace itself. Only later, as the conditions were tested in a proper way, it was found that a power factor of only 0.60 was obtained."

Consequently, under the whole of this period, the first furnace was working with a power factor of 0.60, and it was only in January, 1913, shortly before the second furnace was to be started, that the leads were laid differently and the carbon arrangements altered so as to give a better effect.

The arrangement of the transformers and the regulating system remained unaltered, however, as their change would have caused too much expense.

---

[*] A second part of the paper was also read, but has not yet been published. The first part, which is discussed in this article, has been published in *Teknisk Tidskrift*, December, 1913

The voltages on the secondary side could be regulated between 50 and 78 volts.

These appear to the present author to be too high average values. Compared with other three-phase furnaces, operating under conditions which would call for a higher voltage than required in a closed iron reduction furnace, it is found that the highest voltage required when starting up and while the furnace is still cool is 62 volts, while the normal working voltage after the first two or three hours, with a normal slag, is just under 50 volts, or even down to 45 volts. Hence it seems very likely that a regulation of from 30 to 65 volts would have been much more advisable, perhaps with a small auxiliary voltage raiser for a few per cent of the total power only, to be resorted to in cases of emergency, to break through the resistance of a stubborn charge.

It is true that such a lower range of voltage on the secondary would have rendered the construction of the transformers more difficult and would have increased the cost of the plant at first, and it is quite likely that this consideration may have tempted to instal the higher rating; but on the other hand, with a plant as the one in question, it seems a dangerous policy to save at the start and to risk the life of the enterprise in the end.

According to the paper, the Electrometallurgical Committee which visited the plant in April, 1913, when some of these faults had been corrected, carried out some measurements on the second furnace. The power factor was then up to 0.91 and the electrical efficiency 0.885 per cent at a pressure of 78 volts.

At 50 volts, however, it was found that the normal load on the furnace was unattainable and both the power factor and the efficiency were low (though the actual figure was not stated).

The consequences of the above statements are that as far as the first furnace is concerned 33 per cent, at least, of the total power contracted for was not available in the furnace, on account of unsatisfactory arrangements.

The present author thinks that the above conclusion is not strictly proven to that extent, as the lowest working figure is not given; and although the power factor was rather low, it would mean wattless current which is, of course, not paid for, unless a lump sum is paid for a certain quantity of power, held available at the supply works, but this is not stated.

The second furnace was started in March, 1913, and showed the advantage of a better power factor and higher efficiency, at least as far as the higher voltages are concerned.

That the output of this furnace, however, in spite of this, was not higher than 1.87 ton pig iron per calculated horse power year during March depends on other causes, which the reporter proceeds to explain later on.

In order to show the results at Hardanger more clearly, some curves are issued, made by the electrical committee and based on the calculated figure of a 70 per cent useful efficiency of the furnace per hp year, arranged for various per cent of pig iron calculated on the charges of ore, limestone, etc. One of these curves is shown in Fig. 1.

The upper curve refers to furnaces in which one has 33 per cent of $CO_2$ in the furnace gases; the lower curve refers to such where the gases are chiefly CO.

Certainly other factors than the percentage of iron alone govern the output, namely the degree of oxidation of the ore and its assay in general, the analysis of the pig iron and the slag, etc., but as the percentage of iron is the most important, the other factors have been so far left out of consideration, and the diagram as shown has been adhered to, in order to simplify the understanding of the conditions.

For comparison a few points from other plants are drawn in, namely from the results at Trollhättan ($T_1$ and $T_2$), from Strömsnäs trials (also at Trollhättan) marked (S), from Uddeholm ($U_1$ and $U_2$) and the results from Hardanger (H) during the period March 2 to March 28.

During the last mentioned period at Hardanger, no gas circulation was used in the furnace, wherefore these results actually belong to the lower curve, and from this will be seen that the furnace was only utilizing about 70 per cent of the power supplied; a higher figure is very unlikely to be obtained with this furnace under the prevailing conditions.

It is to be remembered regarding these figures that they refer to the furnace in full operation during the whole period, so that the 70 per cent do not include any stoppages or heating up, repairs, etc. Also it is calculated on the total energy actually supplied to the furnaces, not on the amount which must stand available at the transformers for emergency, etc.

The author of the paper calls this figure of efficiency "apparent" efficiency, which should not be regarded as the efficiency of the plant and should not be laid as basis for estimating the whole results of the works. This is only natural, as the figure obtained for any one single furnace during a short period cannot be regarded as a measure of the conditions of the complete plant, since the furnaces and periods of smelting differ; besides power may also be used elsewhere than on the furnace terminals.

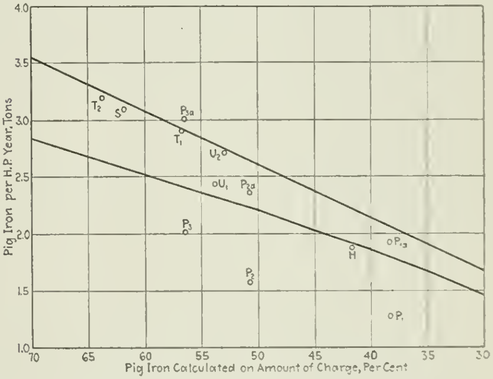

FIG. 1—RELATION BETWEEN POWER CONSUMPTION AND PERCENTAGE OF PIG IRON IN CHARGE

All values given in the diagram No. 1 are figures based on this principle.

The work carried on at Hardanger may be divided up into three campaigns or smelting periods, whereby period III is a part of period II, and the yield during these periods are shown in Table I.

Table I.

| No. | During the period | Per cent. of iron against the charge | Tons of pig iron calculated per H P. year |
|---|---|---|---|
| Period I.— | | | |
| | From Nov. 7, 1911, to April 13, 1912 | 38.1 | 1.28 |
| Period II.— | | | |
| | From July 10, 1912, to Feb. 20, 1913 | 50.7 | 1.58 |
| Period III.— | | | |
| | From Aug. 25, 1912, to Sept. 8, 1912 | 56.4 | 2.01 |

The figure for the power in this table is taken from the *primary* side of the transformers and, therefore, include the losses in these as well as in the copper connections and electrical equipment of the furnace.

These results are found in Fig. 1 under the marks $P_1$, $P_2$ and $P_3$.

In consequence of the faults in the electrical arrangements already stated, the actual quantity of power used in the furnace proper only was about two-thirds of the recorded power, and if this is taken into consideration, the figure for the yield may be altered so as to read (about) 1.92, 2.37 and 3.015 tons, respectively, per calculated horsepower year for the three periods, respectively.

The corresponding values are shown in Fig. 1 under $P_1a$, $P_2a$ and $P_3a$.

As will be seen from Fig. 1, the results of the periods I and II stands between the two actual curves, and as the gas circulation is recorded as being rather low, one may be justified in assuming that the "apparent" efficiency in both cases was approximately 70 per cent.

The point "$P_3a$" stands somewhat over the upper curve, but as this gives the "apparent" efficiency of 70 per cent at a gas proportion of 33 per cent $CO_2$ and as the proportion of $CO_2$ is given in average to be 39 per cent one may also here assume an average efficiency of 70 per cent.

Consequently both furnaces seem to have given an "apparent" efficiency of 70 per cent after the losses due to faulty arrangement of connections, etc., have been deducted. It may be mentioned that the measuring instruments in the plant show a slight error, but this is of minor importance on the whole.

It is noteworthy that these results follow the calculated curve fairly well, wherefore it is safe to say that the efficiency of this type of furnace will in the average give 70 per cent apparent efficiency generally.

The diagram Fig. 1 shows clearly how the faulty electrical arrangements influenced the output on the first Hardanger furnace; and not only this, but these arrangements were of great importance upon the other working conditions, at any rate indirectly.

As one of the indirect consequences may be mentioned the large

### Percentage of Scrap

produced. The Electrometallurgical Committee has drawn attention to the difficulties connected with the tapping of the furnace and proper maintenance of the taphole, and that it was often necessary to disconnect one of the phases in order to obtain sufficiently high voltage to melt out the taphole.

This proves that it was difficult to obtain a sufficiently high temperature in the furnace, and this is quite likely, since a furnace which is designed to receive a certain quantity of heat electrically and which is only receiving about two-thirds of the power, will of necessity run rather cool.

The consequences were also inevitable, and it seems quite permissible to lay the chief fault of the high percentage of scrap produced to this cause.

Table II shows the amount of scrap produced:

TABLE II.

| | Percentage of scrap counted on total output | Smelting stopages in per cent |
|---|---|---|
| First Furnace— | | |
| Period I | about 25% | 20.8% |
| Period II | " 20% | 8.5% |
| Second Furnace— | | |
| Period IV, March 3 to March 28, 1913 | " 10% | 14.0% |
| Period V, April 26, 1913, to June 28, 1913 | " 5% | not stated |

The percentage of scrap from the second furnace is visibly smaller than that from the first, and this must be due to the more efficient way in which the conductors are laid and to the better electrical arrangement generally, whereby it was possible to increase the power in the furnace, as compared with the first furnace.

The interruptions in the smelting play, of course, also a considerable part in this respect, but lack of sufficient heat is more important, as is evident from a comparison between period IV and II.

Truly the stoppages are only taken in hours proportionate to the total period, without stating the numbers of stoppages, but we must assume that the figures given represent the approximate influence of the interruptions. What influence this large percentage of scrap has upon the whole economy of the plant is unnecessary to point out. It speaks for itself.

### The Gas-Circulation

The above-mentioned difficulties in obtaining a sufficient heat in the furnace may probably also have accounted for the fact that the gas circulation was discarded subsequently at Hardanger. It was found necessary to increase the heat in the furnace at all cost and as one of the means to do so was the abandoning of the circulating of the gas, this was given up by and by.

The circulation of the gas causes, as is well known, a lowering of the temperature in the furnace cavity, because a certain quantity of heat energy is used up by the reaction of the $CO_2$ with the heated carbon, forming CO, which is a heat-binding process; further, heat is expended by raising the mass of gas up to or near the temperature of the smelting zone, which heat is then carried up in the shaft.

Of course, a part of this heat is recovered through the preheating of the charge, but as the gases strike rather rapidly through the shaft, a good deal of heat is carried further away, outside the furnace. Hence the gas circulation will lower the temperature in the smelting zone and raise it in the shaft, with the consequence that if gas circulation is employed the gases leaving the furnace will contain more of $CO_2$ than otherwise, which again influences the coal consumption and the power consumption in such way that both of these factors will be lower if gas circulation is used.

The author does not prove this statement by figures. It is clear from his reasoning that the coal consumption should be lower, but it is not equally clear that the *total* power consumption for the whole furnace should be lower, although the process is less heat requiring as far as the actual reduction of the ore goes, if the final gas product is higher in $CO_2$. Against this stands the heat expended in dissociating the $CO_2$, raising of the temperature of the gas mass and alteration of the direction of the heat gradient.

This question could without doubt be answered by means of the results obtained at the trials of the Swedish Iron Institute at their plant at Trollhättan, but the author of the paper has not made a comparison.

As the gas circulation was abandoned, in order to obtain a higher temperature, the coal consumption increased from 336 kg coke per ton of pig iron *with* the gas circulation, to about 385 kg *without* same.

The power consumption increased as well, which can be seen from the diagram, Fig. 1, where the lower curve gives a fair indication of the amount of power without the gas, and the upper curve with the gas.

But as the temperature of the furnace was of a much higher importance one had to give up the advantages of the gas circulation and it appears that the management arrived at the conclusion that it would be generally better under the prevailing circumstances to carry out the process without the gas circulation all together, because after alternative runs with and without circulation for a time, it was not used again during the period after December 14, 1912.

But, as will be seen from the above, the circulation of the gas has a greater importance as soon as the conditions are adequately arranged to obtain a good heat electrically in the furnace cavity.

If, therefore, the abandoning of the circulation was justified for the first furnace, in order to raise the temperature the case is different with the second furnace. Since the electrical arrangements had been altered here, it ought to have been possible to obtain the proper heat even with gas circulation, and so obtain the advantages of gas circulation.

As the diagram Fig. 1 shows, when gas circulation is used, so that the furnace gases contain about 33 per cent $CO_2$, the output per calculated horsepower year can be raised by 15 to 25 per cent.

Of course the circulation may cause other difficulties, but as regards the so-called "slig," i. e., the wet or dry, powdered ore concentrate from which briquets are pressed, the experience at Hardanger seems to indicate that their employment offers no particular difficulty which would prevent the use of gas circulation, as it was stated that the average gas pressure was about 300 millimeters water gauge.

Should, however, the conditions be so that all the furnace gases may be utilized for power, etc., one may be able to recover a part of the heat energy expended this way.

### The Ore Used

It has been pointed out from many sides how important it is to use a high-grade ore for the electric smelting and that the content of iron in the charge will greatly influence the electrical efficiency; this is also very fully demonstrated in the diagram Fig. 1.

It is in most cases more advantageous to concentrate a poorer ore for use in the electric furnace, so as to eliminate the bulk of the dead gangue previously; this is as a rule quite clear, since the gangue forms a heavy ballast, which increases the slag and the total losses and taxes the furnace unnecessarily.

If coke is to be used as a reducing agent, it is necessary to work with a very basic slag in order to obtain a pure material. The addition of lime is, therefore, larger, and will cause a decrease of the percentage of iron in the charge, wherefore in that case it is still more important to use high-grade ores; it is also rather important to use an ore with a lower percentage of quartz, so as to avoid a larger addition of lime.

It seems most advisable to use a mixed ore of basic and acid nature, so that the quantity of lime may be minimal on account of the ore. Of course, one must see to it that the quantity of slag will not be too low; this, however, is less dangerous with electric smelting, as the slag is of less importance here than with ordinary blast smelting.

A number of other features of the ore used are more or less essential for good working of the electric furnace; but as the author says, it would carry us too far to discuss these here. Each kind of ore should be carefully investigated in this respect previous to the smelting.

The author is no doubt quite correct in this respect; but as the practical experience has shown, it is very difficult in the daily routine of work to carry out proper investigation in each case, especially if a greater variety of ore is delivered for smelting; much time and a large staff would be required. This was hardly necessary at Hardanger, where ores of fairly even contents without doubt could be obtained.

The price one should pay for the ore is, of course, regulated by the iron content and its adaptability for good smelting, and it is certainly not self evident that a cheap pig iron can be made from a cheap ore. Therefore, the classification of the ore is governed by the actual results of smelting only, local conditions being considered as well.

Four different ores were used at Hardanger, namely, Klodebergs ore, "red sand" concentrate, and briquets from Sydvaranger, all from Norway, as well as ore from Persberg in Sweden.

These ores were used in proportions given in Table III.

TABLE III

| Period | Ore | Per cent Fe in the ore | Per cent of ore charged | Pig iron produced in per cent of charge |
|---|---|---|---|---|
| Period I | Klodebergs ore . . . . | 45 | About 96 | 38.1 |
| | Red sand concentrates . | 64.5 | " 4 | |
| Period II | Klodeberg ore ........ | 45 | " 22 | 50.7 |
| | Sydvaranger briquets... | 64 | " 56 | |
| | Red sand concentrates.. | 64.5 | " 22 | |
| Period III | Sydvaranger briquets... | 64 | " 88.5 | 56.4 |
| | Red sand concentrates . | 64.5 | " 11.5 | |
| Period IV | Persberg ore ......... | 53 | " 56.5 | 44.6 |
| | Red sand concentrates.. | 64.5 | " 43.5 | |

The Klodeberg ore, which was used almost entirely during period I, and also to some extent during period II, contains about 0.3 per cent of zinc, and this caused a certain amount of difficulties at Hardanger; but apart from this, this ore is rather poor and therefore gives, as the table shows, a low output under period I, only 38.1 per cent.

Hence, if this ore is not exceptionally low in price, it appears to be rather unsuitable for a smelting operation in general.

The briquets from Sydvaranger are prominent on account of their high percentage of iron, and also low content of sulphur and phosphorus. They would, therefore, be regarded as particularly suitable for this process, but the price is so high that it is scarcely likely that it will be economical to use this ore as staple ore. It is, however, most suitable for enriching other poorer ores.

It was stated as a considerable disadvantage at Hardanger, that the briquets delivered were falling into smaller pieces and sand, but it is to be expected that this will be improved upon so that the briquets will arrive in a sound condition.

The red sand concentrate is also characterized by a high percentage of iron and low content of phosphorus, and as it probably can be obtained at a reasonable price, it should form a good staple ore. It has, however, the disadvantage that it contains a good deal of sulphur, wherefore roasting is necessary, and this, of course, increases the cost somewhat.

It was intended at Hardanger to roast this ore on the spot and to agglomerate it at the same time. This, however, met with difficulties; although the de-sulphurization was very effective, it was not possible to cause the ore to stick together to any great extent, wherefore it was necessary to charge the ore in a fairly divided state instead of in lumps as intended, and this, of course, caused a considerable alteration in the original smelting program.

In any case it should be possible to smelt a charge with a considerable percentage of concentrate, if no gas-circulation is used, probably even up to 75 per cent of total ore.

The author of the paper does not consider this fact to be a cause of the previously mentioned abandonment of the gas circulation; this is, however, not entirely out of question, as regards the second furnace, where a higher temperature was otherwise obtained, and Table III shows that a certain amount of this concentrate was used during that period.

In spite of the high percentage of Fe in both Sydvaranger and red sand ores during period II the output was, on account of the poorer Klodebergs ore, only 50.7 per cent.

During period III, when only Sydvaranger and red sand ore was used, the output increased to 56.4 per cent.

The reader may be reminded here that in the trial smeltings at Trollhättan and the Strömsnäs Iron Works, the yield was mostly higher, namely, about 62 per cent, and in some cases up to even 75 per cent.

It is, of course, easier to obtain a higher yield when the smelting is carried out with charcoal and a charge which does not require a large addition of lime, as compared with coke-smelting.

The Persberg ore was used during period IV in the second furnace. Although this ore is a good ore in itself, the author of the paper does not regard it very suitable for the case in question, and he gives the following reasons for this opinion.

In the first case, it only contains about 53 per cent Fe, and, secondly, it contains such a considerable amount of silicious matter that a large amount of lime is required to obtain a basic slag, such as is required with electric smelting. This is shown by the fact that although the ore was considerably enriched with the red sand concentrate, only 42 per cent pig iron (in per cent of charge) was obtained; besides the freight cost will no doubt be rather high.

It is, therefore, not said that this ore is unsuitable for electric smelting. On the contrary, where charcoal is used, and a very basic slag is not required, it should give good results if mixed with richer concentrates.

The author proceeds to show by example how important it is economically to use a charge with high percentage of Fe, and compares the results with different ores.

This comparison is best made between a modification of the conditions at Hardanger during period I and corresponding conditions for period III.

As only a smaller quantity of red sand concentrates was charged during these periods, one can regard period I as representing Klodebergs ore with about 45 per cent Fe and period III Sydvaranger briquets with about 64 per cent Fe. We may further surmise that the furnace in both cases is operating with gas-circulation and about 33 per cent $CO_2$ in the issuing gas without any difficulties, and that the apparent efficiency is 70 per cent. Under such conditions the output per year is represented by the upper curve in diagram Fig. 1. During period I, with a charge giving a yield of 38.1 per cent Fe, we should have an output of 2 tons, and for period III, with a yield of 56.4 per cent Fe, we should get 3 tons of pig iron, all calculated per hp-year.

If we assume a price of $8.25 per hp-year (which is quite permissible), we find that power cost per ton of pig iron will be, in the first case, in round figures, $4.12, and in the second case $2.60.

Consequently, the price of electric power alone, per ton of pig iron made from the low-grade ore, is higher by $1.50 as compared with the production of iron from the richer ore.

(The actual difference total is very much higher, which will be shown in Table X, which is given in the second part.)

Furthermore, during period I only 43.8 per cent of pig iron was produced from ore proper (this figure is rather low, if the analysis of the ore is considered), and in period III 69.1 per cent. In other words, in order to obtain 1 ton pig-iron one requires 2.3 tons of the low-grade ore and 1.45 tons of the richer ore.

If the extra cost of handling of the larger quantity of ore and slag are duly taken into consideration, as well as other expenses connected with the smelting of a larger quantity of low-grade ore, one is justified to conclude that for the case in question the Klodebergs ore should only demand one-half, at the most, of the price of Sydvaranger briquets.

### Electrode Consumption

The consumption of electrodes at Hardanger, compared with other works, is shown in Table IV, where the consumption is given also for the works at Uddeholm and the before-mentioned furnace belonging to Strömsnäs Iron Works, both in Sweden.

TABLE IV.

| Plant | Electrode Consumption in Kilogr. | | |
|---|---|---|---|
| | Per ton pig iron | Per day, total 24 hrs. | Per 24, working hours |
| Hardanger, Period I............ | 29.7 | 170 | 215 |
| Hardanger, Period II........... | 16.3 | 156 | 172 |
| Hardanger, Period III.......... | 11.1 | 134 | 138 |
| Hardanger, Period IV........... | 41.84 | 439 | 510 |
| Uddeholm, Furnace I, March 15-December 31, 1912 .......... | About 9.0 | About 151 | About 158 |
| Uddeholm, Furnace II, August 4-December 31, 1912 .......... | " 7.0 | " 135 | " 141 |
| Strömsnäs , Oct. 1-Dec. 31, 1912.. | 2.78 | 58 | 59 |

The heavy figure for period IV is stated to have been caused by an unusually bad delivery of electrodes, and the Electrometallurgical Committee states that the actual consumption of electrodes, after all breakage has been deducted, is only about 14 kg per ton of pig iron, instead of 41.84 kg. This would correspond to about 170 kg per twenty-four working hours.

As the author of the paper does not state anywhere of what capacity the furnaces were in either case, it is not entirely fair to draw a comparison between the plants, as a furnace of a smaller size will give a different figure compared with a larger, though, of course, the consumption per ton of pig iron is a deciding factor in all cases.

It is clear that the consumption of electrodes is greater when a lower-grade ore is smelted, which would perhaps explain the difference between the 14 kg for period IV and 11.1 kg for period III, when a richer ore was smelted, but on the other hand, the electrode consumption is greater when gas circulation is used, which would have had the opposite effect.

It may be presumed that the electrode consumption is increased when coke is used as reducing agent, and in this case the arrangement of the electrodes should be specially considered. This fact seems to be more or less proved by the frequent breakings of the electrodes at Hardanger.

As has been stated in another report, the furnaces at Hardanger carry six electrodes, as is also the case at Uddeholm, while Stömsnäs furnace has only four. The advantage of using six electrodes, which give a better distribution of heat, is obvious when coke is used. But as far as the experience now shows, the electrode consumption is hereby considerably increased.

The electrodes at Uddeholm and Strömsnäs have the same diameter as those in Hardanger, namely, 500 millimeters (about $19\frac{3}{4}$ in.) and as the power consumption does not differ considerably, each electrode has a much smaller working current density when six are used instead of four. In other words, at Hardanger as well as at Uddeholm, a larger electrode diameter than necessary for the energy supply has been used as compared with Strömsnäs, and the question arises whether the electrode consumption would not have been lower if electrodes of smaller diameter had been employed so that the current density per square inch had been the same as in the Strömsnäs furnace.

Sufficient data for a satisfactory reply to this question are at present not available, but the results from Strömsnäs are certainly significant though several causes must have added to the good results in that plant, for example, specially good quality of the electrodes and similar causes.

Luton, England.

# Fine-Meshed Brass Gauze as a Substitute for Platinum in Electro-Analysis

BY D. F. CALHANE AND T. C. WHEATON

The following article describes a successful substitution in several cases of electro-deposition of metals, of brass gauze as cathode in place of the ultra-expensive platinum. The methods of analysis that will be described have been given two years' tests in this laboratory and found to work well in the hands of students. A great deal has been published on rapid methods of electro-analysis using rotating electrodes and in some cases on methods where the torque of a magnetic field is employed to stir the solution and permit of large currents being used.*

Among the first to notice the value of gauze for cathodes was Winkler in 1899, who stated that the use of platinum gauze as cathode in place of the cones, cut down the time to one-quarter, since large currents could be successfully employed.

Frary also made use of cathodes of platinum, silver and copper gauze in his solenoid apparatus. (Jr. Am. Chem. Soc., vol. 29, p. 1592.)

Stoddard (Jr. Am. Ch. Soc., vol. 31, p. 385) confirmed the work of the previous writers and held that with strong currents and no rotation the heat and gas evolution stirred the solution very adequately. This has been found to be true in our work.

It has been difficult to find a good substitute for platinum. Frary, as previously mentioned, used nickel, copper, and silver gauzes in the deposition of zinc.

J. W. Turrentine[1] proposed the use of graphite cathodes and anodes in place of platinum. These worked fairly well, but with high current densities the graphite is apt to flake and become porous. Sherwood and Alleman[2] used a cathode of stamped tin in the determination of zinc, copper, silver, cadmium, and nickel.

Poweck[3] tried mercury-coated zinc or brass gauze electrodes in the determination of zinc with favorable results. In our work a very fine brass gauze of 100 mesh to the inch was employed. It was copper-coated beforehand. The advantage of the brass gauze is that it is obtainable in finer mesh than copper gauze, and so, for a given size, presents more surface, permitting of large current and thus improving the time factor. Further, it is tougher and is comparatively the cheapest gauze that can be used. At retail its present cost is 80 cents per square foot, and this will make 6 electrodes of the size to be described. With proper care they last for a long while.

One set for a class can be discarded at the end of the term and the cost to each student is insignificant. One of these electrodes worth 20 cents has been used for 30 determinations of copper and is still in good condition.

## Preparation of the Gauze Electrodes

The brass wire cloth is cut into pieces $5\frac{1}{4}$ in. long and $3\frac{1}{4}$ in. wide. The longer edges are lapped over and hammered down. The shorter edges of the gauze are bent over a 12-in. loop of No. 22 copper wire, and the ends of the wire twisted together, thus forming a cylinder, weighing about 12 grams.

The gauze cylinder is placed in a caustic bath to remove grease, rinsed and then plated in a copper sulplate solution for a few minutes, using a current of 2 or 3 amp.

The gauze is then washed, dipped in alcohol, dried and weighed.

For ammoniacal solutions a platinum wire insert is used in the copper wire stem, which will otherwise be attacked by the ammonia fumes near the surface of the solution.

Only two pieces, each 3 in. long, of platinum wire are needed. These are attached to the brass gauze cathode and twisted together. Their other end is joined with the copper wire stem. The approximate area of one of these cathodes is 64 sq. centimeters, calculated from the formula $S = 2\pi Deb\sqrt{\frac{l}{n}}$ (Winkler, Berichte, 32, 2192), where $S$ is area, $D$ is diameter of the wire, $l$ is length of gauze strip and $b$ is its width, or height of the cylinder, and $n$ is number of meshes per sq. centimeter.

The area is not the whole factor responsible for the efficiency of the gauze, as a plain surface 5 x 3 in. would offer nearly 97 sq. cm. surface. It undoubtedly lies in the nature of the surface of a gauze facilitating the rapid elimination of hydrogen, with large currents, thus giving a stirring effect and increasing the rate of migration near the surface of the gauze. Investigation of this problem will be carried out in this laboratory.

The procedures and results in the cases of copper, nickel, and zinc determinations will be given.

Analyses for copper were made from silver alloys, German silver, nickel-copper alloys and copper scale that was contaminated with iron and other impurities.

It was found in the case of silver and copper determinations in potassium cyanide solution that at low potentials between 2 and 3 volts for the deposition of the silver, the brass gauze could not be used as the zinc dissolved, and silver was deposited.

The potential separation of silver from copper in cyanide solution was carried out with platinum gauze and then the copper was deposited on brass gauze at 12-15 volts pressure and a current of 1 to $1\frac{1}{2}$ amp. Time, one hour.

| Wt. Cu. deposit | Per cent copper |
|---|---|
| 0.012 | 9.11 |
| 0.0122 | 9.10 |

The procedure in the analysis of copper scale was as follows: About 0.75 gr. of the sample was dissolved in nitric acid. This solution was evaporated to soft dryness and 10 or 15 c.c. of water added. Then the acid still present was neutralized with ammonia and the solution then made acid with $H_2SO_4$ and 4 drops of $HNO_3$ added. The solution was diluted to 150 c.c. and electrolysed, using a platinum wire spiral as anode and the brass gauze as cathode. The spiral was made by coiling up 10-12 in. of thin wire weighing about 1 gram to the foot.

Some of the results obtained were as follows:

| Wt. sample | Wt. deposit | Per cent copper |
|---|---|---|
| 0.4628 | 0.3366 | 72.730 |
| 0.8292 | 0.6035 | 72.780 |
| 0.8097 | 0.5908 | 72,980 |
| 0.8428 | 0.6118 | 72.600 |
| 0.7710 | 0.5610 | 72.75 |
| 0.6781 | 0.4945 | 72.800 |

The current employed was 3 to 4 amp for the first ten minutes and 1 amp for $\frac{3}{4}$ of an hour. A complete analysis could be carried through in $1\frac{1}{2}$ hours. The deposits were excellent, bright and adherent. The above analyses were selected from the work of the Senior class in Chemistry.

Analyses for nickel were made from various materials, e. g., nickel-copper alloys, German silver, nickel anode scrap and resistance wire. In the analysis of German silver alloy, using the brass gauze cathode, it was found possible to deposit completely between 0.3 and 0.4 gram of copper in 45 to 50 minutes, using a current of 5 amp for seven minutes and 1 amp for 40 minutes.

[2] *Tr. Am. Ch. Soc.*, 1907, 29: 1605-1074.

[3] Smith's Electro-analysis, 1911-119.

| Wt. sample | Wt. deposit | Per cent copper |
|---|---|---|
| 0.5040 | 0.3017 | 59.86 |
| 0.5045 | 0.3020 | 59.82 |
| 0.5000 | 0.2995 | 59.90 |
| 0.5052 | 0.3026 | 59.91 |
| 0.5076 | 0.3043 | 59.97 |

The following procedure was observed in the electrolytic determination of nickel using the brass gauze cathode: About 0.5 gram of the sample is dissolved in a 250 c.c. evaporating dish with 5 c.c. of nitric acid (sp. gr. 1.2). The dish is covered with a watch glass and finally heated on the steam bath when the metal completely dissolves. The solution is then evaporated to dryness. The residue is treated with 4 c.c. of sulphuric acid (sp. gr. 1.84) and heated over an iron plate to expel nitric acid. Twenty c.c. of distilled water are added to the cooled residue, and the dish heated to 60 deg. C. to dissolve all the sulphates.

In a tall 150 c.c. beaker the brass cathode and platinum wire spiral anode are placed and all connections made for a 1 amp current to flow.

The acid sulphate solution is neutralized with ammonia and 30 c.c. excess of strong ammonia added together with a. solution carrying two grams of ammonium sulphate. This solution is poured into the 150 c.c. beaker through a funnel. The current starts at once and the metal is deposited on the gauze, thus preventing any solution of the brass cathode. The cell is now switched over on to a large rheostat and 4 amp allowed to flow for five minutes, which deposits the larger part of the nickel in this time. At the end of five minutes a current of ½ amp is switched on and allowed to flow for the rest of the time necessary to deposit the remainder of the metal. At the end a few drops of the solution are tested for nickel with $H_2S$. A flexible wire is attached to the cathode and this loosened from the binding post and raised slowly from the solution washing with a stream from the wash bottle. The lower edge of the cathode is finally raised from the solution, breaking the electric circuit. The electrode is immersed in distilled water, then in alcohol, and dried at 100 deg. C.

The following data gives results of analyses performed as just explained.

| Wt. charge | Wt. deposit | Per cent Nickel |
|---|---|---|
| 1..0.5823 gr. | 0.5129 | 88.08 |
| 2..0.5919 gr. | 0.5212 | 88.05 |

| Gauze used | Wt. sample | Wt. deposit | Condition | Per cent Nickel |
|---|---|---|---|---|
| 1..Platinum | 0.5983 | 0.5372 | Good | 89.80 |
| 2..Brass | 0.5474 | 0.4917 | Good | 89.82 |
| 3..Platinum | 0.4979 | 0.4368 | Good | 89.76 |
| 4..Brass | 0.5318 | 0.4797 | Good | 89.89 |

The first two analyses were of nickel drillings. The following four examples were analyses of borings from nickel anode scrap. The current was 4 amp for the first five minutes and ½ to ¾ amp for the rest of time, averaging one hour for the maximum time. The deposit were in all cases bright and firmly adherent. It may further be seen that the brass gauze cathode gives exactly as good results as the expensive platinum.

In the zinc analyses a large number of determinations were made, using pure zinc, crystallized zinc sulphate and other zinc bearing material, as alloys such as German silver, impure zinc dust, etc. In all, over 30 determinations were carried out. The solution used was sodium zincate. It was prepared as follows:

The sample was dissolved in dilute nitric acid and then evaporated to dryness. The dish was then heated over an iron plate with 4 c.c. of strong $H_2SO_4$ (Sp. gr. 1.84), leaving the zinc finally as sulphate. The residue was moistened with a little $H_2SO_4$ and taken up in 25 c.c. of water. The following equations show that 4 moles of NaOH are required for 1 part of zinc. A three per cent excess over calculated amount was weighed out.

$$ZnSO_4 + 2NaOH = Zn(OH)_2 + Na_2SO_4$$
$$Zn(OH)_2 + 2NaOH = ZnO_2Na_2 + 2H_2O$$

It was found convenient to make up a solution of standard NaOH of 2½ to 3 normal strength and run in the desired number of c.c. to answer approximately to the calculation for amount of NaOH desired. Say .25 gr. zinc is present, then

$$160 : 65.4 : : x : .25 \text{ whence } x = 6.13 \text{ grs.}$$

of NaOH. Adding 3 per cent excess we have

$$6.13 \times .03 = 0.1839 \text{ gr.}$$
$$6.13 + .1839 = 6.31 \text{ grams of NaOH.}$$

Say the solution of NaOH carries .1 gram of NaOH per c.c., then $\frac{6.31}{.1} = 63.1$ c.c. of solution required.

The gauze cathode and spiral anode were placed in a dry beaker, as in the case of nickel analyses, and the hot solution of zincate poured in through a funnel, the current starting to flow at once. A film of zinc is at once deposited on the surface of the gauze and oxidation prevented. The end of the zinc precipitation may be ascertained by attaching a clean copper wire to the cathode binding post and immersing the end in the solution. If no zinc covering appears after a reasonable time the precipitation is considered complete.

The following are the results of some of the analyses for zinc:

| Wt. substance | Cathode | Wt. deposit | Condition | Solenoid | % zinc |
|---|---|---|---|---|---|
| 1..1.1626 | Brass gauze | 0.2768 | Good | ...... | 23.817 |
| 2..1.0449 grs. | " " | 0.2488 | Good | rotated | 23.81 |
| 3..1.0394 | " " | 0.2476 | Good | rotated | 23.82 |
| 4..1.1429 | " " | 0.2720 | Fair | rotated | 23.80 |
| 5..1.1429 | " " | 0.2720 | Good | not rotated | 23.80 |

The stated amount of crystallized zinc sulphate was weighed out in each case $ZnSO_4.7H_2O$.

In analyses 2-3-4 the solution was stirred by the magnetic field. In 1 and 5 no stirring was employed.

In analysis No. 1 the time was 25 minutes, 5 amp for the first five minutes and 1 amp for 20 minutes.

In No. 2—magnetic stirring—time 35 minutes, 4 amp 15 minutes and 2 amp 20 minutes.

In No. 3, 40 minutes with stirring, 4 amp 10 minutes, 2 amp 20 minutes, 0.5 amp for 10 minutes.

In No. 4—the time was 32 minutes, using magnetic stirring—4 amp for 2 minutes and 0.5 amp for 30 minutes.

In No. 5, no magnetic stirring, time 32 minutes, 4 amp for 2 minutes and 0.5 amp for 30 minutes.

From the results in analyses 4 and 5 it is seen that the magnetic stirring by solenoid does not materially hasten the deposition or improve the character of the deposit.

With the zinc analyses the best procedure was found to be a temperature for the solution of about 60 deg. C., a current of 4 amp for first 5 minutes and 1 amp for rest of time. For an average weight of deposit of 0.3000 gr. of zinc 4 amp for 5 minutes and 1 amp for 35 to 40 minutes was sufficient. The deposits were light-colored, non crystalline, and firmly adherent.

### Summary

It has been shown that the fine-meshed brass gauze is just as efficient as the platinum gauze.

That the time factor for the brass gauze with still electrolyte is very nearly as good as the platinum gauze with magnetic stirring. In fact, the difference in favor of the magnetic stirring is almost negligible.

The brass gauze has been successfully used in the electrolytic determination of copper, zinc, and nickel in various alloys. It gives a very cheap substitute for platinum, costing on the average only about 30 cents per electrode as compared with $19 for a similar platinum electrode at the present price of platinum.

Investigations as to the use of the fine-meshed brass for the determination of other metals will be continued in this laboratory.

## Concentration of Carnotite by Wet and Dry Methods

A year or more ago, when the carnotite deposits of Colorado and Utah began to attract considerable attention, a number of investigators realized immediately the desirability of effecting a physical concentration of the ore. The comparatively low grade of the ore, the distance from market and expense of transportation, pointed to this necessity. It was not surprising that practically all of the individuals engaged in this work hit upon similar schemes for concentration, but no publicity was given their methods at the time for the reason that they desired to keep them secret.

A little later the Bureau of Mines began an investigation of the deposits to ascertain their value and extent, and the methods of mining and treatment. *Bulletin* 70, recently issued by the Bureau, contains a preliminary report on uranium, radium and vanadium, and gives considerable information on the subject that has not been published hitherto. In addition to describing the deposits and giving the production and prices, the *Bulletin* gives information on methods of testing for radioactivity, and a review of methods of treatment and analysis. **R. B. Moore** and **K. Kithil** are the authors of the *Bulletin.*

The carnotite ores mined and shipped contain between 2 and 3 per cent $U_3O_8$ and several per cent $V_2O_5$. The ratio of radium to uranium in carnotite is about 10 per cent below the normal, which is 1 part radium to 2,940,000 parts uranium. The methods of concentration and results obtained by the Bureau are given below.

### Necessity for Concentration

In the course of investigations of these uranium and vanadium ore deposits it was found that much low-grade ore was left in the mines, and thus lost, and that there was great loss in hand sorting. Since the market demand is for a material containing at least 2 per cent uranium oxide, the miner, that he may ship no ore below this limit, eliminates all ore that in his opinion contains less. As a result much low-grade ore and also some shipping ore are left in the mine or are thrown on the dump. By concentrating the low-grade ores at or near the mine these wastes can be reduced. There is no doubt that the ores can be concentrated. Tests made on a small scale substantiate this statement.

In concentration by mechanical means the dry as well as the wet method may perhaps be used to advantage, as little or no water is available in many places where these ores occur. As formerly stated, most of the deposits are far from a railroad, so that wagon hauls are long and expensive. By concentration the bulk of low-grade ore to be hauled can be reduced and at the same time the percentage of mineral in the concentrate raised to a marketable point. Thus a saving in hauling and freight rates is effected, and the concentrate on account of being richer should bring a better price. Low-grade ores thrown on the dump or left in the mine constitute a natural waste. Much of the low-grade material left in the ground during former operations and perhaps much of the dump material can never be recovered. Much of the ore thrown on the dump disintegrates on exposure to the air, so that much of the valuable contents is washed or blown away. Some of the minerals in the dump rock are liable to be leached out by the rain.

### Wet Concentration

The carnotite ores are of great importance, especially on account of their uranium and radium content. Carnotite, which contains both uranium and vanadium, is a yellow, crystalline, pulverulent material, with a specific gravity of 4.136. It occurs in white sandstone as an incrustation on the faces of joints and fractures and is deposited around and between the individual grains of the sandstone, often strongly adhering to the even surface of a grain. The size of these grains varies greatly, but is generally from a little less than 0.1 to 0.2 mm. in diameter.

In concentrating such an ore the rock should be broken and the pieces reduced to about 40 to 80 mesh with crushers or rolls, the crushing being accompanied by rubbing in order to loosen the carnotite from the sand grains. Further attrition should be applied to the 40-mesh material by convenient means. Fine grinding should be avoided, as it produces too much slime.

If the crushed and rubbed material is washed in a revolving tank or trommel provided with a rubbing device, the particles of carnotite that are in suspension can be drawn off after the grains of silica have settled in the tank or cylinder. As some of the carnotite is carried down by mechanical action with the silica in settling, more water should be added and the operation repeated as many times as may be profitable. With such a treatment a large part of the valuable minerals can be extracted.

The slime is washed into settling tanks or other suitable device, and the water after the settling of the slimes can be used over again, as will be necessary in the arid districts, where most of the deposits are located and where water is scarce. Enough water can be collected and stored away for this purpose from seepage, springs, and during rainy days, and in many cases a wet treatment can in this way be made possible.

### Results of Wet Concentration Tests

Tests have been made of ore taken from the dumps at various claims. In one instance this ore contained 2.02 per cent $U_3O_8$ and 2.32 per cent $V_2O_5$. Concentration by wet method gave the results stated in Table I:

*Table I Results of Concentrotion by Wet Method*

| | Quantity, Grams | $V_2O_5$, Per cent. | Weight of $V_2O_5$, Grams | $U_3O_8$, Per cent. | Weight of $U_3O_8$, Grams |
|---|---|---|---|---|---|
| Ore ............... | 1,943 | 2.32 | 44.08 | 2.02 | 39.348 |
| Concentrate ...... | 191.3 | 9.92 | 18.976 | 8.84 | 16.91 |
| Residue .......... | 1,751 | .... | ...... | .... | ...... |
| | 1,942.3 | .... | ...... | .... | .... |

Loss in concentration, 0.7 gram. Concentration ratio = 10.156 : 1. Extraction from ore by concentration, $V_2O_5$ = 43.035 per cent.; $U_3O_8$ = 43.08 per cent. Ratio of ore to concentrate, vanadium content = 1 : 4 :275; uranium content = 1 : 4.376. Ratio of radioactivity, measured in the electroscope, ore to concentrate = 1 : 4.56, which shows that the concentrate is 4.56 times more radioactive than the ore.

Other tests made with ore containing less $U_3O_8$ and $V_2O_5$ have shown that an extraction can be made with a proportionately similar result.

*Table II—Result of Concentration of Vanadium-bearing Sandstone by Wet Method*

| | Quantity, Grams | $V_2O_5$, Per cent | Content of $V_2O_5$, Grams |
|---|---|---|---|
| Ore ........................... | 400 | 5.57 | 22.28 |
| Concentrate ..................... | 85 | 17.35 | 14.75 |
| Residue ......................... | 315 | .... | .... |

Concentration ratio = 4.72 : 1. Extraction = 66.2 per cent.

The result given in Table II was obtained with a reddish-brown vanadium-bearing sandstone from Utah.

The ore was crushed to the size of the grains, rubbed, and then washed in cold water. The slimes thus obtained were settled and decanted or filtered.

According to electroscopic measurements, and by comparison with a standard material of known $U_3O_8$ content, it was found that this ore contained approximately 0.71 per cent $U_3O_8$ and the concentrate contained 1.62 per cent.

In concentrating this vanadic sandstone the content of vanadium was therefore raised to 17.35 per cent $V_2O_5$ and the concentrate can be sold in competition with the Peruvian patronite. In addition the uranium and the radium can be easily extracted from this ore. Some of the vanadium can not be extracted mechanically; it probably exists in the sandstone as roscoelite, which is bound in the silica.

### Dry Concentration

Where water is scarce a dry process can be adopted for low-grade ores. As good concentration with a dry as with a wet process can not be expected, but an equally efficient if not a better extraction can be obtained.

In a dry process the rock should be reduced with crushers and rolls as nearly as possible to the size of the grains of the sandstone. Much of the carnotite can be obtained by sifting the crushed material through a 120 to 150 mesh screen. Care must be taken to collect all of the dust, as this is richest.

Good results can be obtained by using an air current to blow the finest particles into a dust chamber, in which they are collected. The air current must be steady and evenly expanded, so that the coarse particles will drop out of it, and strong enough to completely lift the material. The coarse material should be carried along with the current for some distance, so that as much as possible of the powdery material can be freed and blown from the coarse grains, which should finally drop without carrying the powder with them. These particles should fall into a discharge spout and thence into bins or other suitable devices. The powdery materials, which carry the valuable minerals, is collected in dust chambers. These chambers must be perfectly tight. Much valuable mineral has been lost in sampling shipments when the sampling device had no arrangement for saving the dust.

A number of machines that doubtless could be used for the dry separation of these ores are now on the market. Another method of dry concentration of low-grade ores consists of simple sifting, with previous rubbing, of the crushed ore. The ore is reduced with crushers and rolls to about 40 mesh and is then passed over an oscillating 150-mesh screen. The undersize from the 100-mesh screen is concentrate. The oversize is carried to a device in which the sand grains are subjected to a thorough rubbing, which removes from the silica the adhering fine particles of carnotite.

*Table III—Results of Dry Concentration by Sifting with Previous Rubbing*

| | Mesh of sieve | Quantity, Grams | $V_2O_5$ content, Per cent | Weight of $V_2O_5$, Grams | $U_3O_8$ content, Per cent | Weight of $U_3O_8$, Grams |
|---|---|---|---|---|---|---|
| Ore | 40 | 500 | 2.40 | 12.25 | 2.24 | 11.20 |
| Concentrate | Under 150 | 134 | 4.66 | 6.24 | 4.42 | 5.92 |
| Residue | Over 150 | 169 | 1.60 | 2.70 | 1.53 | 2.58 |
| Residue | Over 80 | 197 | 1.50 | 2.95 | 1.37 | 2.68 |
| | | 500 | | 11.89 | | 11.18 |

Concentration ratio ore: concentrate = 3.73 : 1; extraction $V_2O_5$ = 50.85 per cent; extraction $U_3O_8$ = 52.85 per cent.

In the experiment stiff wire brushes rubbing against a steel plate were used with success for the attrition. The entire material was then brought over two screens, one overlying the other; the upper screen being 80 mesh and the lower one 150 mesh. Table III clearly shows what results can be obtained by such a process. The screens must be encased and all of the dust must be collected. The dust from the sifting operation and that which remains in suspension in the dust-proof screen boxes can be blown from these boxes by suitable means into dust chambers and then added to the concentrate.

A concentration by this dry method on a small scale gave the results shown in Table III. Care must be taken in crushing the ore for either wet or dry concentration that little, if any, of the dust-like material is lost. Dust chambers should be attached to the crushers, or the latter should have air-tight casings and the material should not be removed until the dust has settled.

### Cost of Concentration

The factors to be considered in a calculation of the cost of concentrating the ore by a wet method are:

1. Cost of concentration: (*a*) Water supply; (*b*) Cutting wood for fuel for power and drying (or cost of gasoline if that is used for fuel); (*c*) Hauling of fuel or gasoline; (*d*) Wages for concentrator men.
2. Amortization of equipment for concentration (pro rata of tonnage of material treated per annum for such equipment and for management.

Two men, at $3 a day each, should be able to operate a small plant. The cost of water supply should not exceed $2 a day. The cutting of fuel or cost of gasoline should not be more than $2 to $2.50 a day. The hauling of the fuel would probably cost $1.50 a day.

On an average, from 10 tons of ore mined only 1 ton of ore with a content of over 2 per cent $U_3O_8$ is obtained by hand sorting. From the other 9 tons, thrown on the dump, about 5 tons of low-grade ore can be separated for concentration. Assume that such low-grade ore contains, on an average, about 1 per cent $U_3O_8$ and 1.5 per cent $V_2O_5$. With a concentration ratio of 10 to 1, half a ton of shipping ore should be obtained. The total extraction of mineral by a wet method should be about 50 per cent, and the grade of the material obtained would therefore be fairly high. In an actual test on such a low-grade ore the percentage of $U_3O_8$ in the concentrate was found to be about 4.5. This should, of course, command a proportionately higher price.

The cost of concentration by the dry process is approximately the same, less the cost of the water supply.

The cost of concentration, including maple charges for amortization and for management, should not exceed $20 per ton of concentrate. These figures are conservative and probably the ores can be concentrated more cheaply.

The average cost of mining with present methods at the rate of 10 tons of ore a day with 6 men and the hand sorting done by the foreman is about $30 per ton of shipping ore. This figure does not take into account the powder used in blasting, the wear of tools, etc. If the grade ore is utilized by means of concentration, the expense of mining is thereby increased little, if any, and only the additional cost for the concentration has to be taken into consideration, the charges for sacking and hauling the concentrate to the station being the same as for a ton of ordinary ore.

From the above it will be seen that through utilizing the low-grade ores the average tonnage per year could be increased 50 per cent with little extra expense. But as the uranium and vanadium content of the concentrate would be at least double that of the average ores shipped, the total production of uranium and vanadium from these ores would be doubled. For various reasons it is hardly to be expected that all of the waste material can be utilized, and therefore such a large increase will probably never be actually obtained.

Perhaps several of the operators could combine and install an equipment for mechanical concentration and treat their low-grade ores in a central plant, especially where several operators are in the same district and the claims are near each other. With such a plant in use the production of marketable ore at the present rate of mining could be increased by about one-half without increasing the cost of mining and with only the additional expense of concentration. This increase can be obtained by treating material that hitherto has been lost.

The assumption, which has been made by many of the dealers, that by concentration a large part of the radium content of the ore would be lost, is entirely without foundation, as no such losses of radium in the concentrate can occur from any mechanical treatment of the ore. This has been proved by the tests of the concentrates. Undoubtedly the statement has reference to chemical concentration, in which, of course, such losses might occur.

## The Power Problem in the Electrolytic Deposition of Metals

A joint meeting of the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, and the New York Section of the American Electrochemical Society was held in the Engineering Building on the evening of January 9, 1914, President Mailloux of the American Institute of Electrical Engineers being in the chair. Each of the three societies was represented by a paper, Mr. Lawrence Addicks defining the electrochemical problem, Mr. F. D. Newbury discussing the electrical engineering side of the problem, and H. E. Longwell the mechanical side.

### The Power Problem in Electrolytic Refining of Copper

This was discussed by Mr. Lawrence Addicks, Superintendent of the U. S. Metals Refining Company, Chrome, N. J. By far the larger proportion of the world's copper is electrolytically refined, and this work is almost exclusively an American industry, centered chiefly in large plants on New York Harbor. These plants are being steadily extended as the annual production of copper increases, and present a power problem well worthy of special attention.

For a copper refining plant we have the following power limitations imposed by present practice:

(*a*) Direct current.

(*b*) Say 8,000 to 15,000 amperes.

(*c*) Say 100 to 200 volts per circuit.

(*d*) Resulting in 800 to 3,000 kw. units—1,000 to 1,500 in present installations.

(*e*) Circuits electrically independent, to avoid cross leakage.

(*f*) Constant current; somewhat variable voltage—say ± 20 per cent.

(*g*) Steady current load night and day.

(*h*) Steam needed for heating electrolyte.

(*i*) Plants of from 3,000 kw. to 9,000 kw. should be considered.

The reasons for these limitations are as follows:

(*a*) *Direct Current:* This is obviously required by the nature of the process.

(*b*) *Amperage:* This is fixed by the current density and the electrode surface per tank. (This paper considers only the so-called multiple system of refining, where the electrodes in a tank are in multiple and the tanks on a circuit in series.) The current density is fixed by a balance between the interest on copper tied up, the cost of power and the difficulties in practical handling of rough deposits.

Fig. 1 shows the approximate relation between cost of power and current density in American practice; the high densities, of course, call for cheap water power. Twenty amperes per square foot of active cathode surface may be taken as representing practice in the vicinity of New York, with an ampere efficiency of 90 per cent and an average consumption of about 1 kw. hour at the switchboard per 6 lb. (2.7 kg. of copper).

Electrode surface per tank has been steadily increased until 30 pairs of electrodes, three feet (90 cm.) square, are used in one case. This calls for a current of 30 x 3 x 3 x 2 x 20 = 10,800 amperes. It is conceivable that higher densities and longer tanks may come into use, so that the author has placed the practical limit at 15,000 amperes, but 10,000 amperes should be taken for a definite discussion.

(*c*) *Voltage:* As we have to deal with a highly conducting electrolyte, containing 10 to 13 per cent of free sulphuric acid, which must be continually circulated to avoid stratification in the tanks, carefully studied construction is necessary to avoid serious trouble from leakage currents. These not only represent wasted energy, as shown by the so-called current efficiency, but wherever current jumps from the electrolyte to a lead pipe or other metallic conductor, a rigidly equivalent quantity of copper is deposited thereon and when traversing acid-soaked wood of relatively high resistance, a quantity of heat sufficient to cause a fire risk may be generated. It must be remembered that nearly the entire electrical energy produced at the generators appears as heat in the tanks. It can be readily appreciated that high voltages greatly aggravate these difficulties. While the author has suggested 100 to 200 volts as the range per circuit, he favors the lower limit and does not believe voltages higher than 150 to be good practice.

(*d*) *Kilowatts:* $10{,}000 \times 150 / 1{,}000 = 1{,}500$ kw. for our typical case. This is a little larger than most of the units at present installed, but represents the probable size for a new installation.

(*e*) *Circuits:* The statements already made regarding current leakage indicate the undesirability of any electrical connection between generators, and the author believes it would be necessary to use motor-generators instead of rotary converters in any A.C.—D.C. scheme distributing power from a large unit over several circuits.

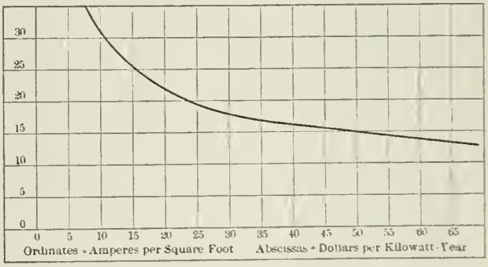

FIG. 1—RELATION OF CURRENT DENSITY AND COST OF ENERGY

(*f*) *Uniformity:* The first principle to be observed in the operation of an electrolytic refinery is uniformity of conditions. The process is very delicate and, while simple in theory, economy depends upon the successful balancing of many conditions to obtain the best results.[1]

In consequence, the current should be held at a fixed value, following variation in the resistance of a circuit with the voltage. Hand control of the field of shunt wound generators is adequate, as the changes in resistance are very gradual. An exception to this statement is the case of cutting out sections of tanks for several hours when drawing copper. It is also necessary to carry up to 2 per cent insoluble-anode tanks, to correct the gradual accumulation of copper in the electrolyte, and as these require about six times the normal voltage for operation, they cause an appreciable variation in the total resistance of the tank house when they are added or withdrawn. To cover this range a field control of our typical generator from 120 to 180 volts at 10,000 amperes will be required. Of course, there will be times when partial or excessive loads will be carried to meet slack or congested supplies of copper, but these conditions are not normal and need not be met with economy.

---

[1] Transactions American Electrochemical Society, 5, 119 (1904)

(*g*) *Load factor:* The operating conditions as described amount to practically 100 per cent load factor for both momentary and 24-hour loads.

(*h*) *Warming electrolyte:* Electrolytes have a high positive temperature coefficient of conductivity. As this amounts to about 0.5 per cent per degree F. (0.9 per cent per 1° C.) and as the electrolyte represents about half the ohmic resistance of the circuit, it is evident that its temperature must be considered. In general, the electric energy dissipated in the tanks will maintain a temperature of 90 to 100° F. (32°-38° C.) and it has been found economical to add sufficient steam in closed coil heating tanks to keep the circulating electrolyte at an average temperature of about 130° F. (54° C.). Exhaust steam can be used, and roughly an amount equivalent to one-fourth of the steam supplied to the engines is required. Additional steam is required for light and power, compressed air, pumping and the manifold requirements of a refining process of which electrolysis is but one step, so that figuring for the moment on the use of live steam for heating the electrolyte, only about one-half the total boiler capacity is used for electrolytic power generation. On the other hand, waste heat boilers attached to the reverberatory furnaces which form a necessary part of every refinery will generate more than enough steam for heating the electrolyte, etc.

(*i*) *Size of plants:* American copper refineries vary from 4,000,000 lb. to 35,000,000 lb. (1,800 to 6,000 metric tons) monthly capacity. At 6 lb. (2.7 kg.) per kw. hour our 1,500 kw. generator would take care of 6,500,000 lb. (3,000 metric tons) per month. Eliminating the smaller plants and allowing for some future extension of the larger ones, we should consider from 2 to 6 circuits of 1,500 kw. each, or 3,000 kw. to 9,000 kw. equivalent to from 13,000,000 to 39,000,000 lb. (6,000 to 17,500 metric tons) copper per month.

Turning now to present practice in the vicinity of New York, we find a very cheap source of fuel in No. 3 anthracite "buckwheat" at $1.75 per long ton ($1.715 per metric ton) delivered. Using this fuel, steam can be produced for about 15 cents per 1,000 lb. (33 cents per metric ton), including all operating expenses, but excluding administration, taxes, depreciation and interest charges. With this base price for steam, a kilowatt hour can be safely figured at 0.4 cent on a similar basis, allowing for auxiliaries and a reasonable departure from ideal conditions in everyday operating. In fact, 0.3 cent can be approached with first-class conditions.

Present practice is to use moderate superheating and vacuum, with the highest-grade reciprocating engines. At the Raritan Copper Works four-cylinder Nordberg triple expansion engines have recently been installed, while at the Chrome plant of the U. S. Metals Refining Company a triple expansion unit using a compound Hamilton-Corliss engine with a Rateau turbine for the third expansion is being tried out. Previous installations have been chiefly confined to compound condensing units. Final figures for these recent installations are not yet available, but Fig. 2 shows about what can be expected from a 1,200-kw. unit of each type, excluding steam for operating condenser.

The Chrome installation is of particular interest on account of the successful commutation of 6,000 amperes (the engine-generator and turbo-generator running in parallel) at 1,500 revolutions per minute by a Rateau-Smoot generator.

The installation cost of such power plants may be roughly taken at $100 a kilowatt, including the disproportionate boiler equipment and auxiliaries.

The plant of the future may consist of gas-driven units, of large-capacity alternating-current turbo-generators driving motor-generators of smaller size, of compound reciprocating engines exhausting into a trunk main from which exhaust steam turbines are fed, of multiple expansion reciprocating engines, of turbine-driven unipolar generators, or of some combination of these. Spare units must be provided in sufficient proportion to give absolute reliability of service.

### Prime Movers for Electrolytic Generators

In his paper on the mechanical side of the power problem in the electrolytic deposition of metals, Mr. **H. E. Longwell**, consulting engineer with the Westinghouse Machine Company, of East Pittsburgh, Pa., said he would confine himself to a general comprehensive survey of the problem from the hilltop of common sense. "In dealing with any technical problem, common sense is most useful; common sense combined with special technical knowledge is doubtless better; but technical knowledge without common sense is disastrous."

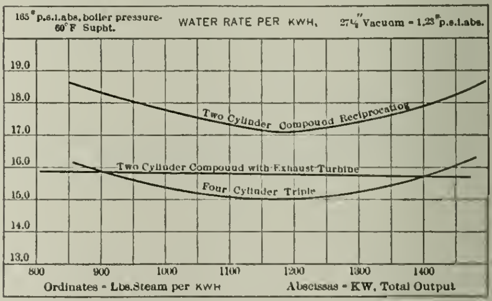

FIG. 2—WATER RATES OF VARIOUS PRIME MOVERS

Mr. Longwell pointed out that any engine the exhaust steam of which is fully utilized can be considered as operating at 100 per cent efficiency. Comparing the performance of a steam-turbine plant with a gas-producer installation, each made up of 1500-kw. units and operating at high load-factors, the author estimated that, using a good grade of fuel containing 14,500 lb-Fahr. heat units per lb., the gas-producer plant would probably show a saving of ½ lb. of coal per kw.-hr. over the consumption of the steam-turbine station. With coal at $3 per ton, this saving of 2 tons per year would effect an economy of $6 per kw.-year, to gain which an extra investment of about $50 per kw. would have to be made over and above the cost of the steam-turbine plant.

Making annual allowances of 8 per cent for interest, 1 per cent for taxes, 1 per cent for insurance, 2 per cent for maintenance and 8 per cent for sinking fund, 18 per cent would be required to insure a return on the investment. As 20 per cent would be desirable, Mr. Longwell pointed out that the saving of $6 per kw.-year effected by the gas-producer units could not be justified unless the differences in initial cost were $30 or less per kw. of installation.

Although it is common practice in copper-refining plants to allow 50 per cent of the steam for the main generating units, 25 per cent for the auxiliaries and 25 per cent for heating the electrolyte, the author declared that since the auxiliaries extract but little useful heat from the live steam, their exhaust can be used advantageously for heating, so that the entire amount for auxiliaries and heating need be only about one-half that required for the main prime movers. In the case of one copper-refining plant which he cited as turning out 500 tons per day the waste heat from the flue gases of the reverberatory furnaces alone is capable of furnishing 50,000 lb. of steam per hour. This steam represents about 40 per cent of that required to run the entire plant and is sufficient for all the requirements of the auxiliaries and the heating of the electrolyte.

Commenting on the theoretical advantages of arranging reciprocating compound engines to exhaust into low-pressure turbines, Mr. Longwell pointed out that the low-pressure turbine costs about 75 per cent more per kw. than the complete-expansion unit. Few triple compound engines, he thought, are enough better than two-cylinder units to make the addition of the intermediate cylinder worth while.

The development of a highly efficient transmission gear for turbines has now made possible the efficient turbo operation of direct-current generators. Several of these geared sets have already been in continuous service for several years, the best known examples being those at San Diego, Cal., Cleveland, Ohio, and Louisville, Ky. While a turbine-driven direct-current unit is more expensive than an equivalent direct-current alternator, it is nevertheless cheaper, said Mr. Longwell, than the combination of turbo-alternator and rotary converter advocated by another speaker.

With careful supervision a really good turbine-driven plant of 6,000 kw. to 9,000 kw. should be built for about $75 per kw., "more or less." Burning coal at $3 per ton and allowing 10.5 per cent for investment charges, it should be possible with capable and reasonably economical management and careful operation at 100 per cent power-factor to produce energy at the switchboard for 4.3 mills per kw.-hr., "more or less."

### Electrical Equipment for Electrochemical Processes

The electrical side of the power problem was discussed by Mr. F. D. Newbury, of the Westinghouse Electric & Manufacturing Company, in a paper on "sources of direct current for electrochemical processes."

The problem involved in producing direct current for electrochemical processes was outlined, and the difficulties are pointed out.

Of the methods of power supply using steam turbines that are available, it was shown that:

(a) Direct-connected d-c. turbo-generators are available only in relatively small units, and cannot be designed as conservatively from the commutation standpoint as is desirable.

(b) Unipolar generators driven by turbines have proven unsatisfactory on account of current collection difficulties.

(c) The standard medium-speed d-c. generator connected to a high-speed turbine through gearing affords a satisfactory unit.

(d) The combined a-c. turbo-generator and converter unit probably affords the best all-around method. It is economical, reliable and flexible. Its particular fields of application are where large units and long transmissions are required.

In waterpower plants, direct-connected d-c. generators and a-c. generators with converters are available. The combined a-c.-d-c. equipment is usually the most reliable and economical. With reciprocating engine units there is no reason for considering other methods than the direct-connected slow-speed generator.

### Discussion

The three papers were discussed together and the discussion was extended, lively, and interesting. Besides President Mailloux, there participated in the discussion Messrs. F. L. Antisell, H. B. Coho, J. B. F. Herreshoff, J. B. Herreshoff, F. A. Lidbury, C. A. Roush and C. H. vom Baur.

Mr. **F. A. Lidbury** said that a plant having an ultimate capacity of 120,000 hp., mentioned by one of the authors, was hardly typical of ordinary electrochemical industries. Only for the manufacture of aluminium are such plants conceivable at the present time. Most electrolytic plants of importance, the aluminium industry being excepted, have a power consumption somewhere between 1000 hp. and 10,000 hp. The electrochemist does not consider it prudent to put, if he can help it, all his eggs into one electrical basket, and consequently in even the largest electrolytic installations (still excepting aluminium plants) the size of units does not often exceed 1000 kw. Under such conditions the conclusions will be different from those reached for a 120,000-hp. plant.

For instance, Mr. Lidbury said, it will no longer be correct to say that "in very few plants can water-wheel generators be located near enough to the electrochemical plant to justify the installation of direct-current generators." It is obviously true that where transportation or other conditions demand the location of the electrolytic plant at a considerable distance from the powerhouse, direct-current generation will be out of question in any case, but where no such condition is involved, it will usually be found not only feasible but the only rational scheme. Mr. Lidbury showed in some detail why for ordinary electrochemical plants he considered direct-current generation quite feasible instead of alternating-current generation with rotaries. "The electrochemical engineer is also apt to have an absurd prejudice in favor of simplicity, and occasionally has been known to evince an unaccountable willingness to pay for it. But there are good reasons for this. Generally speaking, he has quite enough operating troubles of his own without desiring to assume, in addition, the operating troubles of a central station superintendent. What he wants in the way of power equipment is something which will be primarily characterized by smoothness, ease and reliability of operation, and he is apt to know by experience that this is not most likely to be obtained by multiplying the electrical links in his chain of power machinery, or the number of points needing continual attention to insure the best operating results."

Mr. **F. L. Antisell**, of the Raritan Copper Company, said that the efficiency at partial loads should not be overlooked, and called attention to the high operating efficiency of reciprocating engines at partial loads as compared with turbine units.

Mr. **J. B. Francis Herreshoff**, the distinguished engineer and metallurgist of the Nichols Copper Company, said they had had quite a varied experience. Their system at first apparently required small units, and these were supplied with high-speed triple expansion engines, of 400 kw. While they were satisfactory, the cost of maintenance was high. Later on they used a couple of 2000-kw. turbine-driven unipolar generators, but they showed a heat loss of some 30 per cent. Then his nephew, Mr. J. B. Herreshoff, conceived the novel idea of employing a low-voltage alternating-current generator, the output of which was rectified, without voltage transformation, by a properly designed rotary converter. The idea did not at first meet with favor among the engineers of the large electrical manufacturers, but was finally accepted and a good many of these machines are now in use for this type of work.

Mr. **J. B. Herreshoff**, who followed his uncle on the floor, said that by doubling the current density twice the amount of copper will be deposited in a given time. This requires double the voltage and thus four times the power, but has the advantage that the electrolyte is automatically kept warm without the use of steam. Although the power requirement is quadrupled, the cost per pound of copper is only doubled. But the objection to the use of this method in electrolytic copper refining is that the deposits are not so smooth, but are apt to be crystalline, more brittle, and this is often a serious matter in handling the cathodes.

President **C. O. Mailloux** said that the statement that the character of a deposit depends upon the current density is true in the sense understood by the speaker, but that as a general proposition it needs some qualification. As a matter of fact, it is possible to obtain good copper and bad copper at any current density from 10 to as much as 1000 amperes per square foot. He had worked this matter out in 1885, when he had to solve the problem of producing electrotype shells at an extremely rapid rate. Even with a current density of 500 to 1000 amperes per square foot beautiful deposits are obtained, if careful attention is paid to the solution, means of circulation, control of temperature, etc.

Dr. Mailloux finally explained the paradox that with a given amount of electrical energy it is possible at least in theory to deposit any amount of copper. The proof is based on the facts that the e. m. f. required is practically the voltage drop due to resistance only and that the weight of deposit depends only on the ampere-hours. Let a number of ampere-hours pass through a single electrolytic cell, then we will get a certain deposit. Now, let us use four identical cells, arranged in two sets in parallel, each set containing two cells in series, and let the voltage at the terminals of the whole system and the current passing through the whole system have the same values as before. Then the current density is reduced to one-half the former value in each cell. The deposit obtained in the same time is twice the deposit obtained in the former case, while the energy (watt-hours or volts × ampere-hours) is exactly the same as in the former case. Now this multiplication of cells may be carried on in the same way further and further, but a point will finally be reached when, although very large deposits are obtained with the given energy, yet the area of plant required and the interest costs on the large amount of copper tied up would prevent the economical use of any lower densities.

Mr. **Lawrence Addicks**, in speaking on the effect of current density, said that the higher the current density the more rapid must be the circulation in order to keep saturated copper solution close to the cathode, as this is the secret of good deposits. But in the rapidity of circulation the copper refiner is limited by the necessity of keeping the silver and gold slime at the anode, without stirring it up and fouling the cathode. Mr. Addicks also put in a good word for the reciprocating engine driving a direct-current generator as against the turbine, with its alternating-current generator, transformer, rotary converter and booster.

Mr. **C. H. vom Baur** discussed the possibilities of oil engines for electrochemical purposes. Oil from fields recently discovered in Mexico can be sold in New York, he said, for less than 3 cents a gallon, so that such engines can produce a killowatt-hour for 0.45 cent.

Mr. Addicks in closing the discussion pointed out that the oil engine employs a fuel which, compared with coal, is in the hands of a small selling group, and he also questioned whether such internal-combustion engines have the reliability necessary for electrolytic work.

Mr. Longwell said that the gas engine has a great many uses to which it is eminently suited, but in a wholly impartial way he did not think that electrolytic plants were included among these.

Mr. Newbury explained as the reason for selecting very large plants as examples his efforts to show that in such sizes the converter apparatus recommended is really simpler, more reliable, more efficient, and less costly to maintain than the apparently simpler installations consisting of merely prime mover and generator. In sizes of 1000 kw. to 2000 kw. he admitted the turbo-alternator and rotary-converter cannot make a showing against the direct-current generator, provided the electrolytic plant is located near the place of generation.

After the meeting there was a most enjoyable smoker tendered by the American Institute of Electrical Engineers.

## Notes

**Dunn Powdered Coal Burners.**—In connection with the article by Professor G. A. Roush in our January issue it is interesting to note that the Dunn burners have been installed in seven cement plants, four in the East, two in the West, and one in Germany. They are being used by the Carolina Ore Company, at Winston-Salem, N. C., in nodulizing iron ore. An installation that has just been completed for the reduction of nickel and monel metal is giving very promising results. A burner feeding 40 lb. of coal per hour has taken the place of an oil burner consuming 90 gal. of oil per hour, equivalent to 952 lb. of the coal in calorific power giving a saving of almost one-third in heat required, and of still more in cost, since the coal is cheaper than the oil, for this same heating power.

**Electric Steel in England.**—According to a consular report, the first English plant devoted exclusively to the manufacture of electric steel is being erected by the Stobie Steel Co., of Sheffield, on the banks of the Tyne at Dunston near Newcastle. Two furnaces, of 15 and 5-tons capacity, respectively, will be used for melting and refining, and a smaller furnace will be built for producing ferro-alloys. Suitable laboratories will be provided for testing and micrographic purposes. The plant is to be in operation this month.

**Electric Tin Smelting.**—In its issue of January 17, 1914, a prominent American mining paper publishes an article on "Electric Tin Smelting," stating that it is "reproduced from an abstract in the *Mining Journal* from *La Revista Minera y Metalurgica de Madrid*, 1913, based on the experiments carried out by H. Harden in Cornwall and described in the *Elektrotechnische Zeitschrift*. If we add that Mr. Joh. Harden's article appeared originally in METALLURGICAL AND CHEMICAL ENGINEERING in the issue of September, 1911 (Vol. IX, page 453), the record of the travelings of this article through different countries and different languages until its return to New York, some two years later, is complete.

**The discovery of platinum in Germany** is reported by Consul Thomas H. Norton, of Chemnitz. The discovery was made at Wenden, Westphalia, in a district where base metal mines are abundant. Analyses of many borings show the presence of platinum in amounts varying from 0.9 to 1.9 troy ounces per cubic yard of rock. An area of 500 acres has been examined by drilling and found to contain platinum-bearing rock.

# The Present Status of the Wood Turpentine Industry*

BY E. H. FRENCH AND JAMES R. WITHROW

In treating a subject that has as many phases as this one, it will be necessary to discuss briefly an allied industry, namely, that of gum turpentine as distinguished from wood turpentine, in order that the reasons calling for the development of this latter industry may be seen with the proper perspectve.

That the wood turpentine industry is at present at an extremely low ebb is unquestionably true. Nevertheless, it is likewise true that its scientific development is an economic necessity for certain localities, in order that waste may be conserved, that the products from waste replace those from the fast disappearing pine and fir forests and that cut over land may be cleared at a profit instead of at a loss. Therefore, in this instance, as is often the case, necessity compels development.

The fact that thousands of dollars have been expended and lost in the incubation of this industry has been due, in our opinion, to three main causes, any one of which in itself would account for failure; first, the lack of practical scientific engineers experienced in this or analogous fields, second financing for the sale of stock and securities rather than product, and third lack of efficient marketing organization. It must also be borne in mind that, owing to the number of different processes, there was caused a lack of uniformity of product, which naturally tended to increase selling costs. Except to the U. S. Navy little, if any, wood turpentine has been sold on thorough specifications. There has as yet been no real attempt by manufacturers to effect a general standard, although a few years ago the producers of the practically defunct steam process turpentine attempted to standardize their product.

One of the important influences that tended at first toward the development of the industry and later proved extremely detrimental was the speculative nature of the naval stores market. This was made up entirely of gum turpentine and rosin, upon the prices of which the relative wood turpentine values were determined. This market in the past has been subject to violent price changes, a fluctuation of from 30 cents to over $1 per gallon having been experienced, and this was due almost wholly to speculation. Naturally, therefore, during the upward swing of prices an unnatural development occurred, and plants using costly processes and with inefficient management were profitably operated and exploited. It followed, of course, that when the national government, through criminal prosecution, put a stop to excessive speculation, a corresponding reaction occurred, ruining many concerns which required abnormal prices for financial success.

Unreasonably high prices not only encouraged the development of the wood turpentine industry, but also caused an expansion in operations by the gum turpentine manufacturers, so that a larger percentage of trees were boxed, causing overproduction.

### Gum Turpentine

The method of producing oil of turpentine from the resins of coniferous trees consists in cutting a broad, wedge-shaped notch or cup at the base of the tree and removing the bark immediately above the notch for about 18 to 24 inches. The resin exuding from the peeled area runs into the cup at the bottom and is collected from time to time. Each succeeding season the barked area is increased until it reaches about the height of one's head, usually taking five or six years. As many as four "boxes" are thus cut on one tree, depending on its size, permitting only enough of the original bark to remain to prevent the death of the tree.

After collecting sufficient quantity of the resin, it is distilled in a copper still, usually a "fire still," equipped with live steam jet or a water supply. The turpentine thus produced is not carried farther in any refining process, but is ready for the market. The residue in the still is the rosin of commerce and is barreled at the still. The dross obtained by filtering sticks, dirt, etc., from the rosin is in many places being worked into the cheaper grades of rosin. With rosin at an average price, it is generally figured that to make the operation profitable, about 42 cents per gallon must be obtained for the turpentine.

The marketing of the products is done through "factors," as they are called—that is, companies or individuals who contract with the producers for their output, supply them with funds for payrolls, etc., and advances when necessary. These "factors" take the product when produced, but usually have no other connection with the producer. Savannah, Georgia, is the leading naval stores center in the world, and usually Savannah prices are accepted as the standard. Jacksonville and Pensacola, Florida; Brunswick, Georgia, and New Orleans, Louisiana, are also large "factor" centers for this industry.

This method of producing turpentine is generally conceded to give the best turpentine and rosin, but, unless more scientific methods are very widely adopted, the time is fast coming when it will be necessary to supply these products from another source, for present methods of operation are coming to be looked upon as directly antagonistic to all ideas of conservation under American lumbering conditions, as they so weaken the trees that the loss from windfalls is extremely large. In fact, many large lumber companies have given up boxing for this reason, and also because they feel that the growth of the young tree is retarded.

Modifications of the old "boxing" methods are being used in some places. Metal cups are substituted for the box cut in the base of the tree, and it is claimed that the loss from windfalls is considerably reduced by some of these modern improvements. At least one large Southern lumber company is at present experimenting on 5000-acre units in order to determine definitely, if possible, the merits of these new cups and other modifications as to yield and influence on windfalls, and also to decide the effect "boxing" may have on finished lumber.

### Wood Turpentine

Wood turpentine came into commercial notice about the year 1900. The name was, and is, applied to the product obtained from dead and down timber, a waste product called "lightwood." The live or green wood is not so suitable for this manufacture, owing to the moisture content and also to the fact that the bark still remains. Stumps, however, are very valuable, as they contain a much larger proportion of resins than "lightwood." Nevertheless, the cost per cord of stump wood is considerably more, as the stumps usually require the additional expense of removal by explosives. The cost per cord of "lightwood" at the works will run from $2.00 to $3.00, making, however, no allowance for its value as waste, while stump wood will vary from $3.50 to $5.00 per cord, the price depending on acre stumpage and hauling distances. The manufacture may be divided into five general processes—steam process, solvent process, alkali process, bath process and distillation process.

Before entering into a description of these various methods, we desire to emphasize the statement that the manufacture of wood turpentine necessarily will become of far-reaching importance in the future. This is for the reasons that it is utilizing an absolutely waste product and is at the same time clearing cut-over lands and rendering them fit for occupancy.

---

*A paper read before the American Institute of Chemical Engineers.

We wish also to emphasize the statement already made that many past failures were due to the unreasonable speculative condition of the markets. Abnormally high prices of naval stores induced promoters and unscrupulous persons to capitalize their concerns on the earning capacity during this period, thereby making them "stock jobbing" propositions rather than legitimate manufacturing institutions. This kind of financing, while apparently expanding the industry, really retarded development, as the energies of the management were expended primarily at the office end at the expense of the manufacturing organization.

We have seen from time to time figures of promoters regarding yields and manufacturing costs of the different processes which are not in accord with the results obtained from continuous operation. It may not be entirely without value, therefore, to cite some comparative yields and operation costs in the different processes. This is especially true, since there does not appear to be any published data of this nature.

While the records themselves of individual plants would be interesting, such records are often misleading, and in view of actual or possible competition the location of plants themselves must be withheld. In submitting data as to yields, values and productive costs we have compiled them mainly from the actual results obtained during continued operation of a number of large plants. As so many elements making up these figures are variable, owing to location, construction and raw material, our endeavor has been to average them so that a comprehensive idea may be had as to actual results obtained commercially.

*Steam Process.*—This process was the first to be extensively placed in commercial operation and is very simple in its construction and handling, consisting merely of hogging the wood and placing it in a steel cylinder, usually holding about a cord, distillation being carried on with live steam and under varying pressure. However, there was probably little difference in results whether a maximum of five pounds or twenty pounds pressure was used. Distillation was carried forward until oils ceased to be obtained in quantity.

It should be borne in mind that there is a decided variance in the resinous content of wood, therefore, it was quite possible to make a selection that would run as high as 30 gal. of turpentine to the cord. We believe the following figures, however, based on a cord of long leaf yellow pine lightwood, weighing 3500 pounds, would be the average:

| | |
|---|---|
| Turpentine, 9½ gals. at 35 cents | $3.32 |
| Pine oil, 3 gals. at 35 cents | 1.05 |
| Total value of products | $4.37 |

Production cost per cord:

*Production Cost per Cord.*

| | |
|---|---|
| Wood | $3.00 |
| Labor | 1.00 |
| Barrels | 0.42 |
| Freight (approximate) | 0.20 |
| Selling commission | 0.25 |
| | $4.87 |

The fuel cost is only the labor of handling the treated chips. However, there is no allowance made for the office, upkeep, depreciation insurance, etc. Therefore, it can be seen that the steam process necessarily, in order to be profitable, demands a market price considerably in advance of the present markets.

The price of wood turpentine is always a few cents per gallon under that of gum turpentine. The quality of the product produced by the steam process, however, is excellent. Our opinion is, nevertheless, that at least 50 cents per gallon is necessary as a minimum for successful operation.

*Solvent Process.*—In the early development of this process the wood was subjected to the old steam treatment and subsequently treated with carbon-disulphide for the recovery of rosin. The loss of solvent rendered it impractical. In the next stage of development the wood was hogged and placed in digesters for the recovery of turpentine and pine oil. Then the solvent (a low grade of gasoline) was added, live steam was applied, recovering some turpentine, pine oil and solvent by distillation, and the dissolved rosin drawn off, its volatile matter being recovered by distillation.

This has been improved, subsequently, in some instances by omitting preliminary steaming, adding solvent direct and recovering this with the turpentine and pine oil by live steam in the primary distillation, obtaining rosin alone when the still is drawn. The rosin, however, is soft, and difficulty has been experienced in obtaining a hard product, but this is overcome by subsequent treatment. In either method, a considerable loss of solvent is always entailed, varying from 17 to 30 gal. per cord.

The approximate yields and operating costs per cord are as follows:

| | |
|---|---|
| Turpentine, 9½ gals., at 35 cents | $3.32 |
| Rosin, 400 lbs., at $4.00 per 280 lbs | 5.72 |
| Pine oil, 3 gals. at 35 cents | 1.05 |
| Total value of products | $10.09 |

*Production Costs per Cord.*

| | |
|---|---|
| Wood | $3.00 |
| Labor | 2.50 |
| Loss in solvent at 15 cents (17 gals.) | 2.55 |
| Barrels | 0.42 |
| Rosin barrels | 0.25 |
| Selling costs | 0.50 |
| Freight | 0.75 |
| Total | $9.97 |

Again the actual fuel cost in this process is negligible as use is made of the "treated chips." No allowance is made here for insurance, upkeep, overhead and interest charges, refining costs or depreciation; therefore, it is plainly evident that at present market prices, at least until improvement is made in yields or in minimizing costs, there is not sufficient margin for successful operation.

However, it is quite possible that by using the "treated chips" for paper pulp manufacture that this process will be made of commercial value. The operation in this case would have to be maintained on an enormous scale in order to supply treated chips for a pulp plant unit of an economic size. A plant using this solvent system and built on a very elaborate scale was in operation in Southeastern Georgia, and, despite the most advantageous financial backing, was unable to operate profitably on a weakened market, and is now in the hands of receivers.

This citation alone probably would not necessarily condemn the process, but as several smaller plants are either in like position or shut down, it indicates the necessity of research or development if ultimate success is to be attained. As with the steam process, many claims of higher yields than we have above credited are made by interested parties, but these claims are still subject to substantiation.

*Alkali Process.*—This process is essentially one to be applied to the alkali processes for manufacturing paper pulp from resinous woods with the recovery of turpentine and rosin and at the same time improving the quality of the pulp and promoting ease of manufacture. The process is well covered by patents.

The basis upon which this method rests is the fact that the sodium hydroxide saponifies the resins in the wood and the sodium resinate thus formed may be separated from the spent soda pulp liquor by temperature regulation. The wood is handled in the same manner as in soda pulp manufacture, except that after digestion the spent liquor is cooled for the separation of sodium resinate before this liquor proceeds to the evaporators. This product has been so purified and refined commercially, as to produce a good quality of paper size. The resinate may if desired be manufactured into rosin by acid treatment, or destructively distilled, obtaining rosin oils. The turpentine is recovered from the digester blow-off during the digestion operation.

This process is apparently theoretically sound, but requires the outlay of capital to develop thoroughly the mechanical details. Fifty to seventy thousand dollars were expended in one case to demonstrate its commercial possibilities, and some results were obtained. However, the enterprise has not been financially successful and the plant has been dismantled, a fact which may be due to faulty engineering or other causes, and even though the process appears enticing from a theoretical viewpoint the fact remains that the trial was not successful, and there is no process of this kind in actual operation.

Nevertheless, it is our opinion that eventually it will be of commercial importance, and ultimately the combination of the two industries, paper pulp and turpentine-rosin recovery, thus utilizing resinous wood, will be successful. Unusual yields of turpentine are claimed by a Florida plant using an alkali bath, but satisfactory arrangements have not yet been made regarding rosin recovery.

*Bath Process.*—This process must not be confounded with the recently suggested process using a bath or envelope of oil external to the oven for the purpose of heating the same. This external bath process has not been long enough in operation to demonstrate its future, and it will be interesting to note if certain fundamental operation difficulties can be overcome.

By bath process we refer to the process commercially called the bath process which has been in operation for some time, and in which the bath is within the oven, or retort, in contact with the wood itself. Three plants using this method have been built, the first in North Carolina, which has been dismantled; the others at Mt. Pleasant, Ga., and Jacksonville, Fla., which have not been successful under low market conditions, and both of which have gone into receivers' hands within the last few months.

The process itself was divided into two separate general operations. First, the recovery of turpentine and pine oil, or, as styled, "sweet spirits," and subsequently the destructive distillation of the wood itself, although this second operation was not contemplated in the original process.

The operation has a decided advantage over the solvent and steam processes in that it does not require the "hogging" of the wood.

The general construction used in this first operation consists of steel cylinders at Mt. Pleasant, and concrete ovens at the Jacksonville plant, each holding five to nine, 1 to 2-cord steel cars, similar in construction to those in common use in hardwood distillation; thus each oven holds about nine cords of wood. Placed at the side of the oven is a heater equipped with a large cast iron worm connected to the bottom of the oven. To the rear of the heater is placed a large steel or concrete reservoir connected by cast iron pipe to the top of the oven and also to rotary pumps, which in turn are connected to the heater pipes.

The loaded cars are placed in the oven and melted rosin or pitch is run into the reservoir and circulated by the pumps through the heater and the bottom oven connected. This pitch, after filling the oven, overflows into the reservoir and is thus continually circulated through the heater and oven, thereby vaporizing the volatile resinous bodies and without dissociating the wood fibre. The turpentine and oil vapors are carried through a "vapor" chamber where the high boiling liquids that are mechanically carried by the vapor are separated, the vapor continuing to an ordinary tubular condenser, where the crude "sweet spirits" are obtained. Afterward the "sweet spirits" are refined, the products being turpentine, pine oil and a tarry residue. The time required to "treat" a charge varies in the plants mentioned from seven to ten hours, and the product obtained is of high quality, though not so good as steam process turpentine.

At first sight it would appear that in this process the rosin from the wood treated would gradually increase the volume of the bath and rosin be thus manufactured. The reverse of this, however, is the case, as a very serious loss of bath is actually realized. This is, in fact, a serious drawback to the process, and is probably due to the formation of volatile rosin oils when the liquid bath encounters the high temperature of the heater. These rosin oils are volatilized and pass into the "crude spirits" and are lost in the refining residue, as only from 65 to 70 per cent of the spirit is received as turpentine and pine oil. By proper arrangement this difficulty could have been avoided.

This process is also seriously handicapped by the fuel consumption of the heaters and the heavy upkeep for heater pipes and pumps. Nevertheless, with proper design, operation costs would have been much reduced from that actually experienced.

After refining, the results from this "sweet process" could be averaged as follows:

| | |
|---|---|
| Turpentine, 7½ gals. at 35 cents | $2.62 |
| Pine oil, 2½ gals. at 35 cents | 0.87 |
| | $3.49 |

After the charge is withdrawn in this first operation the "treated" wood is placed in ovens similar to those used in the hard wood industry and there subjected to destructive distillation. The results obtained here are very important, as a good market has been created for these products. An average of from 68 to 70 gal. of oils is obtained, together with a like volume of "acid water," the latter a "waste," although its utilization was accomplished just prior to the receivership of one of the mentioned companies. In addition there remain in the cars approximately 900 lb. of charcoal, and there is produced about 10,000 ft. of non-condensible gas per cord which is of fuel value.

This crude distillate above mentioned is called "destructive distillate" or "D. D. product" to distinguish it from the product derived from the resins called "sweet spirits." On refining there are obtained the following products per cord:

| | |
|---|---|
| Tar, 41 gals. at 8 cents | $3.28 |
| Light oil, 6.8 gals. at 12 cents | 0.81 |
| Heavy oil, 10 gals. at 12 cents | 1.20 |
| Charcoal, 36 bushels at 7½ cents | 2.70 |
| From "Sweet Process" | 3.49 |
| Total value of products | $11.48 |

*Costs of Production per Cord.*

| | |
|---|---|
| Wood | $3.00 |
| Fuel | 3.25 |
| Labor | 2.75 |
| Cooperage | 1.00 |
| Selling costs | 0.60 |
| Freights (approximate) | 0.75 |
| | $11.35 |

Again it can be seen that this process handled as it has been in the past cannot be operated successfully on a low market, as no allowances have been made for upkeep, insurance, interest charges, refining costs, management or depreciation. Although the loss in bath is partially made up by the pitch obtained, it can be seen from these costs that improvement must be had before this process can exist during low market conditions. It is not to be inferred, however, that the principles upon which the process is based are entirely faulty. The reasons for its failure appeared to be lack of knowledge as to the chemical nature of the products and troubles consequent to improper construction and operation.

As is common with approaching dissolution, strenuous efforts at improvement were made in this process, and, despite well known prior failures, experiments were completed and operation commenced for the utilization of the waste "acid water" just before the closing of one of the plants. The results proved interesting and promised excellent recovery, as the products recovered, including acetate of lime and wood alcohol, represented a net gain of well over $1.50 per cord.

*Distillation Process.*—As the wood turpentine industry now stands, the destructive distillation process apparently has the best chance of commercial success, as it is not only more simple in construction and operation, but yields more in volume of products. Chemical and engineering skill, nevertheless, are necessary for this success.

The distillation process may be subdivided into three divisions. First, that division analogous to hard wood distillation. This method in its primary operation is very similar in equipment and design to the usual hard wood distillation plant, the wood being placed in steel cars and run into ovens. The products derived from the resins and those from the dissociated wood are collected together, and separation is made during refining, although some attempt has been made at fractional distillation in this primary stage. This method gives a much inferior grade of turpentine, etc., owing to the commercial difficulty of eliminating the pyroligneous bodies, and the product will not answer to the permanganate test, which indicates pyroligneous matter. The tar produced in this operation is usually resinous and for some uses therefore objectionable.

The second division is merely a modification of this process, the ovens being in duplicate, and distillation for the resinous bodies being carried out in one oven, so designed or "set" that the temperature can be maintained approximately uniform. After the resinous bodies have been obtained the "treated wood" is withdrawn and placed in a second oven, and in this oven the distillation is carried at a higher temperature for the destructive distillation of the wood itself.

The third division is that using concrete ovens containing 12-inch heater pipes, running the length of the ovens. These ovens have Dutch-oven connections and the flue gases travel through these pipes, and it is claimed that temperature regulation is more easily accomplished.

In all these processes the products obtained are the same, except so far as the degree of purity is concerned.

The first distillate, or that from the resins in these methods will run on an average 22 to 24 gal. of "sweet spirits." This on refining will give from 50 to 60 per cent, or from 12 to 14 gal. of marketable turpentine, and from 9 to 10 per cent of pine oil, or from 2 to 2½ gal., and also 100 lb. of a very resinous pitch.

The destructive products are the same as those from the "bath process." Thus it can be seen that the gross total in this operation should be materially higher than in the other processes, while the operating expense is very much lower. This, including wood, upkeep and in fact all expense, should not, under proper design, construction and management run over $9.00 to the cord.

The particular objection raised against the destructive distillation process is that the products are difficult to market, and this has been true to a certain extent in the past, but when it is considered that many of these bodies were new to the trade, this condition cannot be wondered at, and at present the marketing is not more difficult than products of other processes. In fact, just now there is an unusual demand for these products.

### Markets

It may perhaps be of interest to call attention to the various developed markets for the D. D. products, for we all realize that the marketing of products is at least equal in importance to the manufacture; and this industry shows many instances where comparative merit of process and operation was wholly lost by inferior marketing facilities, and, on the other, hand, instances in which unsound operation was maintained for considerable time by a remarkably efficient selling organization. The latter cases, while losing ventures to those financially interested, have no doubt succeeded in creating a growing demand for the products as indicated by the prices obtained now for them with many plants closed down.

At the time this article is written tar could easily be sold for 12 cents per gallon, as compared to the 8 cents allowed in the cost data in the article, but which should be considered maximum, as the future, undoubtedly, will increase supplies so as to bring these prices back to a more nearly normal condition.

This fact, however, does show that a demand has been created that did not exist prior to the quite recent establishment of plants of this nature. Perhaps this condition is more clearly evidenced in the heavy D. D. oil, for which 22 cents per gallon is being obtained. The tar demand had in a measure been previously supplied by that known as "kiln tar," made at works using the kiln system for charcoal manufacture from resinous woods.

The product mentioned as D. D. light oil is at present most difficult to market profitably—this is on the market in this form and is used to some extent by manufacturers of disinfectants. However, it has been fractionally distilled and has been used locally as a substitute for gasoline for use in engines and has proven itself to be more efficient than gasoline. The comparatively small amount of this product makes its use in this manner merely of local interest, but it indicates a real value of the product.

The Heavy D. D. Oil has been in consistent and increasing demand, particularly in the paint industry and notably for shingle stains, and also for the manufacture of tar oils, for which there is a large foreign demand. The necessity of an energetic market agency was in one case well illustrated within the past year with this product. One large concern was offering this product for 5 cents per gallon, finding it impossible to market, having nearly 100,000 gal. in storage, while at the same time another company was unable to supply its customers at 18 cents per gallon. Of course, the latter considered the purchase from the former, but feared future competition, in case, as seemed dangerously probable, the former concern should learn of their customers.

The pitch produced in the distillation process and distinguished from the tar has a firm market demand from ship chandlers and also is sold for uses, such as coating silos, rendering them impervious to moisture.

The tar, of course, has its established uses, with rope manufacturers as well as with paint producers, while the charcoal consumption, particularly in the south, is very steady both for domestic use and manufacturing. Of the number of suggested specialties based on the use of tars and oils, doubtless a few will ultimately contribute a steady demand for a portion of these products.

### Cost of Installation

The various processes have in most instances exceeded reasonable installation costs. Undoubtedly the same is true in any newly established industry, and more particularly in cases where, as pointed out in this one, prices could be obtained that were out of all proportion to production costs.

Entire equipment of a steam process plant should come well within $750.00 per cord capacity, while the solvent process complete should be approximately $2,000.00 per cord; this also should be approximately that of the bath system, while the destructive distillation method ought to be very close to $1,500. In making these general estimates neither working capital nor purchase of timber or stumpage is considered.

### Conclusion

When your attention is brought to the fact that the destructive distillation plants alone have been able to survive recent price depression, it is reasonable to conclude that, in the present state of the art, this method has inherent advantages. Nevertheless, in this type of process, there is room for much improvement, particularly in refining and the utilization of waste products ignored in the past. Constructive chemical engineering apparently has, in this industry, opportunity to create an unusually profitable business, provided it utilizes the unfortunate mistakes of the past by combining parts of the various processes.

It is not to be inferred from this article that recommendations are made for the encouragement of any particular process, the motive is merely to outline present conditions, or, broadly, to show cause and effect, and also to show, if possible, that many elements are as necessary in this industry as in any other to attain success. Statements have been made to the effect that failures in most instances were due to lack of real engineering skill, and this is partly true, but lack of skill is not wholly accountable for even the engineering failures, for no amount of theoretical enginering skill can replace the knowledge acquired from continued intimate contact with the going operation.

Neither does this statement take into consideration the marketing organization, which is also an essential and is always confronted with the general economic situation, which does not affect directly the operation.

It can be seen from this outline of the industry that its very existence was primarily due to an unnatural market condition, and as the field for profit and exploitation was so enormous it can hardly be wondered at that unusual activity was had in its promotion.

---

**Butte and Superior** made a new record in milling efficiency in November, 1913, when the concentrates averaged 50.58% zinc and the recovery over 90%. The total production for the month was 10,995 tons of concentrates containing 11,123,000 pounds of zinc.

**Plans and some details** of the new Massachusetts Institute of Technology are announced in the November, 1913, issue of the *Technology Review*: "From the waterside it will present the appearance of a great white city of majestic proportions, with the long vistas of its facades broken by suitable intervals, and relieved by the foliage of shrubbery and trees. The interest of the spectator will center in the broad court extending back a sixth of a mile from the river and leading by terraces to the great colonnaded portico of the central building of the group." The educational portion will be a connected group of buildings three and four stories in height. The arrangement will be flexible to provide for future expansion of the departments.

## Mechanical Refrigeration—I

### Choice of Refrigerants

BY H. J. MACINTIRE

Mechanical refrigeration is a process of cooling by means of a reversed steam-engine cycle. In this cycle external work is done on some agent either by heating a solution directly with steam or by some other means or by compressing the vapor with a metallic or fluid piston. Heat is added to the working fluid at a lower temperature, and is abstracted at the higher temperature—mechanical energy having been supplied between these two processes of sufficient amount to make it possible. In mechanical refrigeration, then, a refrigerant —the special term used in referring to the working agent in this particular thermo-dynamic cycle—has to be employed.

There are certain essentials in mechanical cooling, as far as the working medium is concerned, which usually must be complied with. For instance, the volume of the refrigerant must be reasonably small, otherwise the refrigerating machines become bulky and expensive. The kind of refrigerant chosen must be such as will give readily the desired temperature; it must be cheap, if a new supply is used at the end of each cycle, or it must be of stable composition, if the refrigerant is used continually. With these factors in mind, an analysis of the possible refrigerants will now be made, and the advantages of the more common ones will be considered.

One of the first of the practical refrigerants to be used was *air*. It is without cost, is available everywhere and is harmless if allowed to exhaust or leak out of the system. Yet it is now found in but a few installations and mostly in a modified form called the "dense air machine." The reason for the abandoning of air is because of its low heat capacity, as will be clearly seen on a consideration of a typical example. A pound of air at — 100 deg. Fahr. might be allowed to come into metal contact with brine or other substance whose temperature it is desired to lower.

If the air is allowed to be raised to + 30 deg. Fahr., or a total heating of the air by 130 deg. Fahr., the possible amount of refrigeration would be, per pound, $130 \times 0.24 = 31.2$ B.t.u., and the volume of this pound of air at atmospheric pressure would be approximately 12.4 cu. ft.

Should a closed cycle be employed (the air being used over and over) the volume of 1 lb. of the air leaving the cooling coils may be one-quarter or one-fifth of the amount above, depending on the cooling pressure used. In the last case refrigeration is obtained by the so-called "dense air" cycle. However, even the dense air refrigerating machine is bulky, inefficient, and troublesome to operate and except for unusual circumstances machines using air as a refrigerant are obsolete.

Let us now consider the case of easily condensed gases, i.e., the vapors, and allow the liquid refrigerant to pass into the cooling coils. In order to evaporate this liquid, heat has to be added, and in the evaporation an amount of heat equal to the latent heat of vaporization has to be taken away from the surrounding bodies—the latter thus being cooled by a like amount. The amount of this latent heat, in heat units, depends on the substance and somewhat on the temperature of vaporization, and may be 160 B.t.u. per pound for ether, 360 B.t.u. for alcohol, 550 B.t.u. for ammonia, and 1000 B.t.u. for water vapor. Even in the case of ether the amount of possible cooling per pound of refrigerant is above five times that possible in the case of air, whereas it is only one-sixth of that theoretically possible when using water vapor.

From what has been said it is clear that a very wide range of substances suitable for refrigerants are at hand, and yet the number actually used is small—less than a half dozen, namely, water vapor, sulphur dioxide, carbon dioxide, and ammonia. The method of elimination, and the choice of a possible refrigerant, is suggested by what follows under the topics of cost, chemical and physical properties.

### Cost

The cost of the four refrigerants chosen for our analysis—water vapor, sulphur dioxide, carbon dioxide, and ammonia—is, except for the first one, much too great to allow them to be used in any way except continuously. Therefore, a closed cycle is necessary, and when the working medium has performed its function of cooling it is compressed again, and made to repeat the operation. Water, then, as it is practically without cost, has a great advantage over the other three and, other things being equal, it would be the most acceptable substance for a working medium. Unfortunately the cost is not the only consideration.

### Chemical Properties

The chemical properties of the refrigerant are important as far as concerns the corroding action on metal, safety, and ability to withstand disintegration. Anhydrous sulphur dioxide has been found to attack iron at about 205 deg. Fahr., but this is a temperature which is never reached under normal operation of the compressor. Ammonia corrodes copper and copper alloys, so that this metal has to be entirely eliminated from the ammonia circuit. As far as their action on animal life is concerned (water vapor excepted) the refrigerants under consideration are almost equally dangerous. Sulphur dioxide and ammonia are easily detected by their smell, but carbon dioxide (when pure) is odorless and as much as 1 per cent or two per cent may be present in the air without discomfort. Ammonia has been found to burn at 900 deg. Fahr., and is also perhaps the least stable of the four compounds, hence successive use in the refrigerating system tends toward a slow disintegration.

### Physical Properties

So far this analysis of the refrigerants (except for the cheapness and safety of water vapor) gives no reason for particular preference of any one over another and it remains for a critical consideration of the physical properties to determine what refrigerants are of value in given cases and which are the most desirable under those particular conditions. The physical properties may be compared by considering tables of these vapors in the condition of saturation. Table I and Fig. 1 assemble this data for the several refrigerating media which we are examining.

Referring to Table I: Column 1 gives the latent heat of vaporization for the four refrigerants, assuming a uniform boiling temperature of these of —4 deg. Fahr., this temperature being maintained constant by keeping the pressure in the cooling coils uniform and equal to the amount given in column 10. Columns 2 and 3 contain the values for the heat of the liquid at 68 deg. Fahr and —4 deg. Fahr. In this regard it is assumed that the cooling water available is of such a temperature that the refrigerant may be cooled to 68 deg. Fahr. The corresponding condenser pressure is given in column 9 as well as in the figure.

Column 4, obtained by subtracting the sum of 2 and 3 from 1, gives the net theoretical amount of refrigeration in B.t.u. per pound of the refrigerant at the operating conditions. It should be clear that the temperature of the liquid refrigerant as it leaves the condenser has a decided influence on the values in 4, as the liquid has to be cooled to the temperature at which refrigeration takes place (here —4 deg. Fahr.) before any useful refrigerating work may result. This cooling is done at the partial evaporation of the refrigerant, and the net result is a decreased value for the possible refrigeration per pound of the medium. The desirability of using cool condensing water in the condenser is apparent, although carbon dioxide only seems to be affected seriously by this, as shown in column 5, which gives a percentage ratio of columns 4 and 1.

As a closed cycle has to be used, the vapor in the refrigerating coils has to be compressed and returned to the condenser in order to obtain a liquid again. The usual method of so doing is to pass this vapor into a compressor, similar in design to an air compressor. The capacity of the refrigerating plant will depend on the piston displacement of the compressor and the volume of 1 lb. (the specific volume) of the refrigerant, the ratio of the two being the number of pounds of the refrigerant compressed and condensed per unit time. Column 7 gives the theoretical displacement in cubic feet of such a compressor for 100,000 B.t.u. of refrigeration and column 8 repeats simply the last figures but with carbon dioxide expressed as unity. Assuming the same rotary speed, the compressor using sulphur dioxide would have to be 13.42 times the size required for carbon dioxide and with ammonia 4.95 times, whereas the value for water vapor is absurdly large.

Referring to columns 8 and 9 it is seen that water vapor is out of the question when used in a reciprocating compressor because of the great volume of the vapor accompanied by the extremely low pressure. Sulphur dioxide has a conveniently low condenser pressure even with condenser water of 100 deg. Fahr. or more, which makes it very useful in the tropics, especially as its efficiency does not decrease greatly—a fact which may be made clear by working out column 5 for this temperature. Its slight pressures allow light construction and enable the machine to be made portable if desired. The size of the machine has to be considerably greater than for ammonia or carbon dioxide. The latter requires a much smaller compressor, but the working pressures are excessive. The cylinder and piping frequently have a working pressure of 900 lb. to 1000 lb. or more; and the leakage loss becomes large as a rule. Low refrigerating temperatures, however, are easily obtained.

In America from 85 per cent to 90 per cent of the total mechanical refrigeration is done by using ammonia as the refrigerant. The reasons for this are to be found in the moderate pressures encountered, its efficiency with condensing water of from 70 deg. Fahr. to 100 deg. Fahr., its medium piston displacement, as shown in column 8, and the ease with which the more usual refrigerating temperatures may be reached. Some space, as far as the compressor is concerned, could be saved by using the carbon dioxide compressor and for this reason as well as because slight leaks are not so noxious or harmful it is commonly found in marine and hotel use. For most industrial work, however, for the reasons given, ammonia as the refrigerant is much to be preferred.

University of Washington, Seattle, Wash.

---

The **Third International Congress of Tropical Agriculture** will be held at the Imperial Institute, South Kensington, London, S. W., from June 23 to 30, 1914. The following subjects, among others, will de discussed: technical education and research in tropical agriculture, labor organization and supply in tropical countries, scientific problems of rubber production, methods of developing cotton cultivation in new countries, problems of fiber production, the cultivation and production of rubber, cotton and fibers, cereals and other foodstuffs; tobacco, tea, cocoanuts, etc. The subscription for membership in the congress will be £1. All correspondence is to be addressed to the Organizing Secretaries, Third International Congress of Tropical Agriculture, Imperial Institute, London S. W. The International Rubber and Cotton Exhibitions will be held simultaneously.

## A New Design of Filter Press*

BY ALFRED BURGER

Before describing the new filter press, I intend to give a short survey of the developments in the construction of pressure filters for filtering and washing purposes, and to point out certain lines along which improvements have been made.

If we look back a few decades it seems as though the activities in this branch of chemical engineering had come to a temporary stop with the general introduction of the chamber filter press. This machine had so many advantages that it rapidly found its way into practically every chemical factory and is still in general use to-day. It is a strongly built, reliable and practically fool-proof machine and does do the work for which it is built, though in fact badly, especially since we know that better results are obtainable.

For large-scale operations, however, the chamber filter press had its limitation. Filling and washing took a long time and consequently too many machines were required for handling the slush, and the cost for labor ran up very high. For this reason many plants stuck to decantation or table washing, finishing with a squeeze press. Others which were more progressive tried filtering and washing in the press, but had to give it up.

Judging from the numerous attempts subsequently made to find a cheaper and more convenient way of discharging the solid matter, it appears that the separating and putting together again of the many plates and frames after each cycle plus the cost of labor involved were considered the chief disadvantages of the chamber filter press.

In trying to overcome these drawbacks it was soon found that the chamber filter press did not lend itself very well to such improvements. The only way in which the solid matter can be removed without separating the filter members is by sluicing. This method, though it has proved very successful in some cases, is but a compromise between the old way and something better that was yet to come. Besides, sluicing is only feasible if the solid matter is worthless.

Better results in this endeavor were to be expected from another kind of filter, the leaf type, which was then already in use, though in a primitive form and chiefly for clarifying purposes. It seems as though the inventors of this latter type did not have an adequate conception of the filtering problems confronting engineers in certain chemical and metallurgical fields. Nothing was done by them toward making the apparatus more useful, enclosing the leaves in a suitable shell which would permit an easy removal of the cakes.

The proposition of improving it in this direction was taken up some years later out West, and undoubtedly the great opportunity there revealed has been an active stimulus to the inventors of two types of leaf pressure filters perfected in recent years.

These two are giving very satisfactory results indeed, especially that type of which a model has been exhibited at a previous meeting of the Institute. Yet, if we compare the working of such a modern leaf-type filter with an ordinary chamber press, we find that the superiority of the former is due not to the mechanical discharging but to the greater washing efficiency. Thus the time required for separating the plates and frames and closing them up again at the end of each cycle seems, after all, not to be such a disadvantage as had been represented. The discharging feature, as will be demonstrated later, is in fact a secondary matter.

Besides these successful attempts to solve the problem of discharging the solid matter in a more satisfactory way than is possible in a chamber press, other lines of improvements have recently been taken up with the view of constructing a filter press in which the filtration is followed by a squeezing of the cakes mechanically and to effect filtration at a much higher pressure. But in my judgment no great advantage will be derived from this direction. Owing to the constructional difficulties to be surmounted and to complications of such machines their use will be limited, while filtration under much higher pressure is no more effective.

---

*A paper read at the New York convention of the American Institute of Chemical Engineers.

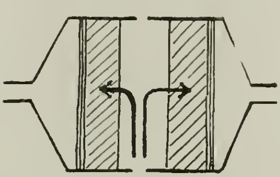

FIG. 1—PRINCIPLE OF WATER PENETRATING THE CAKE IN THE SAME DIRECTION AS THE SOLUTION

Some years ago the writer became familiar with a process of which the filtration of the slush constitutes one of the most important operations, and as the results obtained in the filter presses employed seemed to indicate ample room for improvements, I subsequently and incidentally gave some attention to filter press matters. It seemed to me that not so much the time and labor involved for separating and putting together again the plates and frames, but rather the low washing efficiency of the chamber press was the feature most deserving of correction.

When occasionally filtering the same material through a filter funnel in the laboratory it surprised me that the liquor ran so nicely through the cake, and in proportion much less water was needed for washing the residue free from soluble matter than the big filter press required working with 50 lb. pressure. This observation led me to apply the same washing principle to a chamber filter press which consists of letting the water penetrate the cake in the same direction as the solution. Fig. 1 illustrates this. The cylindrical parts of the two filter funnels facing each other resemble a section through a chamber in a filter press having an opening at the bottom and top. Two distinct cakes are formed which are washed from inside.

To what reason the bad washing in the ordinary chamber press is due has been described before, but let me add, the reversing of the current is not alone responsible for the bad results obtained. Cakes which I have seen seemed to indicate that the inefficient washing, especially in case of slimy solids, is due to a great extent to the uneven filtering soon after fresh blankets have been put in the press. The cakes that begin to form on the wash plate sides are, owing to the continuous good condition of these blankets, considerably denser. The very first deposit is often a relatively hard layer which on reversing the current for washing purposes cracks. Cakes occasionally examined always showed this cracking distinctly (Fig. 2) and a separate testing of the different layers revealed plainly how the water had penetrated the cakes. The hard brittle crust in one instance contained about 6 per cent, the soft central part 0.4 per cent and the left layer 1.2 per cent of soluble matter not washed out.

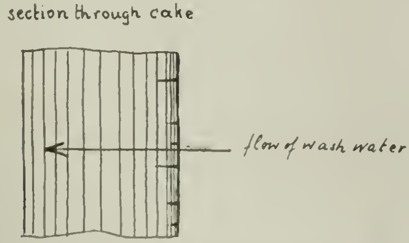

FIG. 2—CRACKING OF CAKES

What I have termed a new filter press is the direct-flow principle, as illustrated in Fig. 1, applied to a chamber filter press of very simple construction. The method of operation is still simpler. Fig. 3 shows a cut through the stationary head and first chamber with pipe connections. The liquid-solid enters from the bottom channel with valve *O* open. As soon as the material begins to overflow, *O* is shut. Filtration starts and is continued until sufficient cake has formed to leave but a space in the center of ½ to ¼ in. Water is then switched on, and after washing has been completed the excess is withdrawn by means of compressed air introduced from the top. Air is then blown through the cakes for a short while when the press is opened and the cakes discharged. Of course, the method just described is not sufficient to insure good results. Certain constructional details are absolutely essential, as otherwise trouble will arise causing complete failure. Now, rather than describing those details I prefer to give a few figures showing the work done by presses in actual operation. Thus I think it will be better appreciated what these improvements amount to.

For filtering and washing an aluminium hydrate precipitate it used to take six hours in the regular chamber press for washing the cakes free from the solution, while with the press of my design one hour is now required. In case of a prussia-blue, washing was reduced from twelve hours to two. A carbonate of lime residue was washed free from solution in less than one-third the time a Dehne press required, and the amount of water needed for doing it was reduced to one-third.

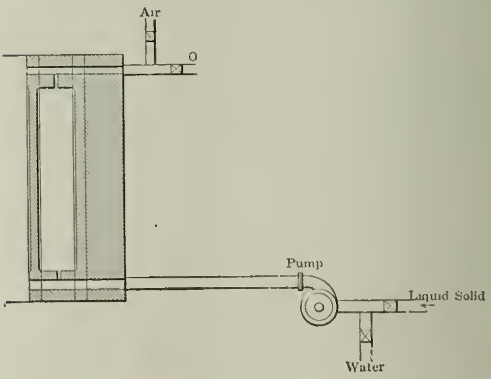

FIG. 3—FILTER PRESS BASED ON DIRECT-FLOW PRINCIPLE

The excellent results obtained induced me to file application for patent for this device. In looking over patent specifications as to improvements on chamber presses I was somewhat surprised to find that apparently nobody before fully realized the great advantages to be gained by this very simple mode of filtering and its general application. I want to emphasize that good results are only obtainable if filtering and washing is carried on without interruption and with steadily increasing pressure. Introduction of air or steam between filtering and washing, for instance, is impossible. Also a clearance must be left between the cakes of at least ¼ in. to facilitate an easy and even distribution of the washing fluid.

Besides these very great advantages over the ordinary chamber press in respect to time and efficiency of washing, there are a number of others as, for instance, lower operating pressure, absolutely clear filtrate, less leakage and less pressure required for keeping joints tight, which means a saving in blankets.

A plate and frame filter doing such efficient work compares very favorably with a leaf-type filter equipped with the best mechanical devices for discharging the cakes. I am able to prove this with the aid of figures obtained from presses working on the same material and under identical conditions.

| | Washing efficiency | Final moisture content | Lbs. of dry solids per sq. ft. filter area per hour |
|---|---|---|---|
| I, chamber press.......... | 20% | 30% | 0.8 |
| II, improved chamber press | 60% | 28% | 3. |
| III, leaf-type press....... | 54% | 36% | 3.5 |

As to the calculation of the washing efficiency of a filter press as given in the table I shall explain this more fully later on.

A glance at the collated figures reveals clearly the inferior work done by the old chamber press. Its washing efficiency is only one-third of that of the two other presses, and consequently the output for unit filter area which is chiefly influenced by the washing efficiency is still less, about one-quarter. It is evident that this press drops out of consideration for processes in which large amounts of material have to be filtered and where wash-water means evaporation.

A comparison of the presses II and III proves that my previous statement as to the capacity per unit filter area being principally determined by the washing efficiency is correct. The difference in the quantity of cake handled per square foot per hour in this particular case was only 0.5 lb., or 14 per cent. This is small, indeed, and will only have an influence in favor of the leaf-type press when huge quantities of material are to be put through, but then it is rather the saving in labor which will enter into consideration. On the other hand the lower moisture content of the cakes obtained in the improved chamber press is decidedly a great advantage whenever the residue is to be dried. That together with the somewhat higher washing efficiency will outweigh the labor item, which is in favor of the leaf-type filter. Moreover, the simplicity of replacing a leaky blanket is a matter not to be overlooked.

* * * * *

In connection with the description of the new filter press just given I intend to add a few suggestions concerning a standard method of putting down the work done by a filter. I think there can be no question as to the usefulness of such a scheme. Filtering is one of the most important operations in many chemical and metallurgical processes, and the machines are so numerous that figures computed in a like manner as to the work done by them would be most interesting and valuable. It would be of help to the engineer interested in some particular process, as well as to the man who is offering a machine for effecting the separation of a liquid from solid matter.

The data given before and which I used for comparing three different types of presses defined pretty well the performances of each machine. One figure relates to the amount of water needed for washing the cakes—no doubt in many cases the most important item—the second tells the condition of the discharged cakes, and the third data gives the amount of material handled per hour and per square foot filter area when operating continuously.

With regard to the amount of water required for practically complete extraction of soluble matter from the cakes, we often hear it expressed in gallons per ton of dry solids. While this is quite sufficient for one familiar with the material worked to do some figuring, it conveys no direct impression as to how efficient washing is carried out. For this reason I prefer to base the calculation of this item on the displacement principle, calling the washing 100 per cent efficient if the volume of water required for practically complete extraction is equal to the volume of solution the cakes contain after they have been built up.

Figs 4, 5 and 6 illustrate this.

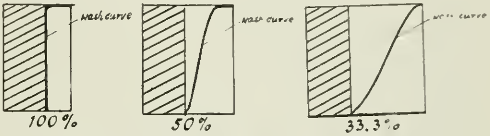
In Fig. 4 (100 per cent washing efficiency) the solution is pushed out of the cake with an equal volume of water.

In Fig. 5 (50 per cent washing efficiency) the solution is pushed out of the cake with twice its volume of water.

In Fig. 6 (33.3 per cent washing efficiency) the solution is pushed out of the cake with three times its volume of water.

A press doing a good work should at least show a washing efficiency of 50 per cent.

The final moisture content gives the amount of water remaining in the cakes when they are discharged. This data will assume importance in all cases where the material has to be dried.



FIGS. 4, 5, 6—100%, 50%, 33.3% EFFICIENCY

The figure as to the amount of solids handled per square foot per hour is interesting as well as important. Interesting inasmuch as it shows—providing the washing efficiency is about equal—to how much those devices for mechanically discharging the cakes amount to; important, because it tells what size filter is required to handle a certain quantity of material in a given time.

68 Bay View Avenue, New Brighton, N. Y.

**Platinum** is worth about $45 an ounce, against $20 five years ago. The United States output of this metal in 1912 was only 721 ounces of crude metal. The world's output for that year was estimated by the Geological Survey to be 314,751 ounces, derived as follows: Russia, 300,000; Canada, 30; New South Wales, 500; Colombia, 12,000; United States, domestic crude, 721; United States, from foreign and domestic matte and bullion, 1300; Borneo, Sumatra and other, 200. The production of the more valuable metals in the United States in 1912, in short tons, is shown in the following table:

| | Quantity | Value |
|---|---|---|
| Platinum | 1.304 | $1,732,221 |
| Gold | 188.108 | 113,415,410 |
| Silver | 4,471.4 | 80,187,317 |
| Aluminium | 32,803. | 15,089,380 |
| Quicksilver | 939.9 | 1,057,180 |
| Nickel | 22,421. | 17,936,800 |
| Tin | 8.4 | 8,850 |
| Copper | 734,052. | 242,337,160 |

**The melting points of some copper alloys** have been investigated by the United States Bureau of Mines, and the results are contained in *Technical Paper* No. 60. The following table contains results of many tests which checked within 5° C.:

| Alloy | Deg. C. | Deg. F. |
|---|---|---|
| Gun metal | 995 | 1825 |
| Leaded gun metal | 980 | 1795 |
| Red brass | 970 | 1780 |
| Low-grade red brass | 980 | 1795 |
| Leaded bronze | 945 | 1735 |
| Bronze with zinc | 980 | 1795 |
| Half yellow, half red | 920 | 1690 |
| Cast yellow brass | 895 | 1645 |
| Naval brass | 855 | 1570 |
| Manganese bronze | 870 | 1600 |

## The Russian Chemical Industry

[*Special Correspondence from St. Petersburg*]

The chemical industry in the Urals has been quite an exceptional business up till recently, partly because of the geographical position of that mining district, and partly because of the economic conditions existing there. If we leave out the industries of the Kam river district the products and by-products prepared at the Urals chemical works generally are consumed entirely by the local concerns, and only a relatively insignificant quantity is sent into the interior market and into Siberia. Only special products, such as bichromate, for which the district holds practically a monopoly in view of the favorable natural conditions, are exported to more distant European and Asiatic Russian markets.

On the other hand, exceptionally favorable conditions would exist for the production of sulphuric acid in the Urals, because of the deposits of pyrites and the fine quality; but is prepared on the spot in very limited quantities, almost exclusively for local requirements, such as the preparation of galvanized iron and the working of copper ores, etc. The relatively small quantity that reaches the markets for various small uses need not be taken into account. As far as is known, in the Urals factories sulphuric acid is hardly used for other purposes, nor are its salts or other derivatives. In truth, at present the general revival of industrial life in the Urals is finding expression in the production of sulphuric acid.

The creation of new galvanized iron factories is causing an extension of existing sulphuric acid factories, and the construction of new ones in the district. Besides this, the organic development of industrial life in the Urals finds its expression in various tendencies in the present chemical industry, showing that it is changing over to a new and more complicated development. The appreciation of the price of fuel, the high cost and insufficiency of labor, are now bringing certain chemical processes to the front which have resulted in the establishment of new chemical factories. As an immediate example we have in view the application of peat for the production of generator gas, and the establishments of dry distillation of wood on modern principles.

The application of peat for the production of generator gas under certain conditions of operation, yields various by-products, amongst these ammonia, which in combination with sulphuric acid, enters the fertilizer industry. One of the largest Urals concerns will shortly begin the extension of its sulphuric acid plant in connection with the production of ammonia from peat.

The question of establishing in the Urals an efficient factory for dry distillation of wood is largely dependent on the question of expensive fuel. The production of charcoal is usually done under very primitive conditions, and a large quantity of valuable products disappears together without profit. The establishment of dry distillation of wood under efficient conditions using the acetic acid and the wood spirit, and perhaps even turpentine, would make it possible to considerably reduce the cost of charcoal for metallurgical purposes.

Considering all these things, the government of the Kyshtim mining district is building a factory for the dry distillation of wood, which in a very short time will be started to work. It is easily understood that the establishment of all these new concerns intimately connected with the conditions of the present day development of the Urals mining industry, must result in the development of associated branches of the chemical industry; both for the purpose of providing the necessary raw materials, and for the further preparation of finished goods. On the other hand, a market must be found for the products; for the Urals chemical industry hitherto has had to work within very narrow limits in this respect.

The most interesting development in respect to technical improvements is the tendency obvious at the moment to utilize the sulphur fumes from the copper roasting furnaces. If these sulphur fumes which are now liberated directly into the open air were taken and resolved into sulphuric acid we should obtain an immense quantity of this product at a very low price. Analogous conditions exist in Silesia, where the recovery of sulphurous gases obtained during roasting zinc blende has resulted in the formation of an immense sulphuric acid and superphosphate industry, which exports from Germany into all directions, to Russia, Austria-Hungary, Servia, Roumania, etc.

If it were possible to establish such an industry in the Urals in connection with the roasting of copper ores, the Russian market would be able to dispose of a colossal quantity of sulphuric acid—two or three times more than the existing demand for it in the country. At first, naturally, it would be difficult to place such a large quantity of acid; but it is thought a large quantity of sulphuric acid could find a relatively easy market in the superphosphate industries of the country in the near future. This is the direction which should be taken by those who are studying the question of waste sulphur fumes. Unfortunately information on the phosphate deposits of the Urals does not tend to encourage the hope of an early extensive establishment of a superphosphate industry there, to yield a cheap manure for our eastern and central districts, where it is so much wanted. In any case the first steps in this direction are now being taken, and judging from the information gathered over the widely extended area, including the Kyshtim mining district, it may be noted that the utilization of sulphur gases recovered from three copper roasting furnaces is already being effected, each of these furnaces burning 2500 poods of pyrites per day.

We are probably entering quite a new era in the development of the chemical industry of the Urals, particularly in reference to artificial manures. And although it is quite true that the analyses of the Urals phosphate deposits is not an encouraging one, they can still be used with a cheap sulphuric acid and produce a superphosphate which will be of greater relative value to the local agriculturist than would be a richer manure after having to pay the enormous cost of transportation from Western or Southern Russia. Thus while Southern Russia becomes an exporter of sulphate of ammonia the Urals is probably entering into a state of independence with respect to artificial fertilizers, which are two very notable developments in the Russian chemical industry.

---

**The Arizona Copper Co.** produced, during December, 1913, 1460 tons of copper.

**The Thomas Mellen Company**, Portland cement manufacturers, Jamesville, N. Y., have broken ground for their new cement stock-house and expect to be able to run cement into the same before February 1, 1914. The building will be of steel and concrete with self-emptying bins. At one end will be located a pack house equipped with Bates-Valve soaking machines. This will be the first of extensive additions to be made to the plant in the next year. Owing to the high quality of the product and the consequent popularity of the brand in Syracuse, Rochester and northern central New York, the company has found the enlargement of their plant necessary. Richard K. Meade, chemical, mechanical and industrial engineer, 203 N. Calvert Street, Baltimore, Md., has been retained as engineer and prepared the plans and specifications for the new stock house.

# Extinguishing of Fires in Volatile Liquids[*]

BY EDW. A. BARRIER

The extinguishing of fires in oils and in most of the volatile liquids has always been a difficult problem, and where fires of this kind occur the results are frequently very disastrous. Our most common extinguishing agent, water, works rather unsatisfactorily upon the majority of such fires, but it is still the only one available where heroic measures are required. Comparatively recently, however, there have been two or three other materials introduced for use as extinguishers which have shown some promise for dealing with these fires.

Not all fires in volatile liquids are difficult to handle with water. When the liquid is miscible with water this extinguishing agent can be successfully used. Examples of this kind are denatured alcohol, wood alcohol, grain alcohol, acetone, etc. Where the liquid is not miscible with water little or no effect is produced except to wash the burning liquid out of the building where it my be completely consumed or, if the quantity of oil is small, possibly to extinguish the fire by the brute cooling effect of a large quantity of water sprayed upon the fire. Soda and acid extinguishers are somewhat more effective than pure water, but even they fail under most conditions. The various grenades containing salt solutions which were formerly extensively exploited are, of course, practically worthless.

The only principles that can be made use of in extinguishing fires in volatile oils are, (a) to form a blanket either of gas or of solid material over the burning liquid which will exclude the oxygen of the air, or, (b) to dilute the burning liquid with a non-inflammable extinguishing agent which is miscible with it.

### Sawdust and Bicarbonate of Soda

To the blanketing type of extinguishers belong sawdust. Paradoxical as it may seem, ordinary sawdust is an excellent extinguishing agent for certain volatile liquids, especially those of a viscous nature. A considerable number of experiments were conducted in the fall of 1912 by the inspection department of the Associated Factory Mutual Fire Insurance Companies, in the extinguishing of fires in lacquer and gasolene in tanks with sawdust, and the results were surprisingly satisfactory.

The liquids were placed in three tanks 30 in. long, 12 in. wide and 16 in. deep; 48 in. long, 14 in. wide and 16 in. deep, and 60 in. long, 30 in. wide and 16 in. deep. The sawdust was applied with a long-handled, light but substantially built snowshovel having a blade of considerable area. In every case the fires were extinguished readily, especially in the ttwo smaller tanks, which were about as large as any ordinarily employed for lacquer in manufacturing establishments.

The efficiency of the sawdust is undoubtedly due to its blanketing action in floating for a time upon the surface of the liquid and excluding the oxygen of the air. Its efficiency is greater on viscous liquids than on thin liquids, since it floats more readily on the former than on the latter. The sawdust itself is not easily ignited and when it does become ignited it burns without flame. The burning embers have not a sufficiently high temperature to reignite the liquid.

The character of the sawdust, whether from softwood or hardwood, appears to be of little or no importance, and the amount of moisture contained in it is apparently not a factor, so that the drying out of sawdust when kept in manufacturing establishments for a time would not affect the efficiency.

It was found that the admixture of sodium bicarbonate greatly increased the efficiency of the sawdust, as shown both by the shortened time and the decreased amount of material necessary to extinguish the fires. A further advantage of the addition of bicarbonate of soda is that it decreases the possible danger resulting from the presence of sawdust in manufacturing plants since it would be difficult, if not impossible, to ignite the mixture by a carelessly thrown match or any other ready source of ignition.

Although the efficiency of the sawdust is greatest on viscous liquids such as lacquers, heavy oils, japan, waxes, etc., in the tests referred to, fires were extinguished in gasolene contained in the smallest tank and also when spread upon the ground. In larger tanks the sawdust or bicarbonate mixture does not work so well since the sawdust sinks before the whole surface can be covered, whereupon the exposed liquid reignites.

### Carbon Tetrachloride

In recent years carbon tatrachloride has received considerable attention as a fire-extinguishing agent. This is due largely to the activity of certain manufacturers of fire extinguishers which use liquids, the basis of which is carbon tetrachloride.

This substance is a water-white liquid and possesses when pure a rather agreeable odor somewhat similar to chloroform. A considerable proportion of the commercial article upon the market, however, contains sulphur impurities which impart a disagreeable odor to the liquid. The substance is quite heavy, its specific gravity being 1.632 at 32 deg. Fahr. It is non-inflammable, non-explosive, and it is readily miscible with oils, waxes, japan, etc. When mixed with inflammable liquids it renders them non-inflammable provided a sufficient quantity is added. Its vapor is heavy, the specific gravity being about five and one-half times that of air, consequently it settles very rapidly.

As an extinguishing agent it operates by both the principles mentioned above, namely, it diluted the inflammable liquid rendering it non-inflammable, or at least less inflammable, and it forms a blanket of gas or vapor over the burning liquid which excludes the oxygen of the air.

It may not be out of place to mention that the claims made by certain manufacturers producing extinguishers which use liquids, the basis of which is carbon tetrachloride, are grossly exaggerated. These preparations, none of which is more efficient than carbon tetrachloride, are not the equivalent of the ordinary water extinguishers for general use on such materials as cotton, wood, paper, oily waste, etc.

On volatile liquids, oils, etc., carbon tetrachloride has, however, shown very satisfactory results under some conditions, but the readiness with which a fire can be extinguished with it depends to a considerable extent upon the skill of the operator and the nature of the fire. In tank fires the length of time that the liquid has been burning is an important factor, and in such cases where the sides of the tank become heated the only way in which the fire can be extinguished is to squirt the liquid forcibly at the sides. If the carbon tetrachloride is squirted directly into the liquid it is much more difficult, if not impossible, to extinguish the fire.

The height of the liquid in the tank is also a very important factor. Where the liquid is low the sides form a pocket which retains the vapor and aids considerably in smothering the blaze. When the tank is nearly full, however, this condition does not exist, and it is then very difficult, if not impossible, to extinguish a fire in a highly volatile liquid, such a gasolene; only the most skilled operators are successful in these cases. The size of the tank or the extent of the fire if upon the floor is, as would be expected, of considerable importance. In tanks larger than about 28 in. by 12 in. more than one extinguisher and operator working at a time are necessary to extinguish a fire in such materials as gasolene. In one test where a tank 60 in. by 30 in. was used no less than seven operators were necessary, and even then it was only with the greatest difficulty that the fire was put out.

---

[*] Slightly abstracted from the December, 1913, issue of the Journal of the American Society of Mechanical Engineers. The author is a member of the Inspection Department of the Associated Factory Mutual Fire Insurance Companies, Boston, Mass.

All of the above remarks apply to carbon tetrachloride in the ordinary one-quart extinguisher as generally sold. It is probable that a large extinguisher which could throw a large stream would prove more efficient, but on account of the great weight of carbon tetrachloride such an extinguisher would have to be specially designed to make it readily portable by mounting on a truck or some similar means. Expelling the liquid by means of a hand-pumping arrangement would probably be unsatisfactory, and it would, therefore, be necessary to force it out in some other way.

A few systems have recently been installed in which an elevated tank containing carbon tetrachloride was connected with automatic sprinklers or perforated pipes located in hazardous rooms where volatile and inflammable liquids are in use. So far as is known none of these systems have as yet been called upon to extinguish a fire, but there appears to be no reason why such a system should not provide excellent protection in special cases. In such systems it would be necessary to consider the safety of the workmen and furnish ready means of escape, since carbon tetrachloride is an anesthetic and where thoroughly sprayed through the air, as from an automatic sprinkler, it would probably produce rapid results.

The nature and effect of the fumes given off when carbon tetrachloride is thrown upon a fire is a subject which has received a great deal of discussion. When the liquid comes in contact with a fire the vapor is partly decomposed, resulting in the evolution of a considerable quantity of black smoke which is undoubtedly finely divided carbon. Pungent gases are also produced which appear to be mostly hydrochloric acid, with possibly a small amount of chlorine. Since carbon tetrachloride contains no hydrogen from which hydrochloric acid could be formed, this substance must be produced by the action of chlorine on the gases arising from the burning material or upon the moisture of the air.

The fumes of carbon tetrachloride, although of a very pungent nature, do not produce any permanent injury under ordinary conditions where the operator can make his escape after he has inhaled all he can stand, but they are distinct handicaps in fighting a fire and are one of the objectionable features to carbon tetrachloride as a general fire extinguishing agent. In large rooms or where a small quantity of carbon tetrachloride is sufficient to extinguish a fire, the gases are, of course, less objectionable.

### Frothy Mixtures

Another method of extinguishing fires in oils and volatile liquids which has recently been proposed and experimented with is that of using frothy mixtures. The idea seems like a very promising one and the tests which have been thus far reported indicate very satisfactory results. The idea was originated and has been developed in Germany. So far as is known no experiments have been conducted in this country.

The process consists essentially in causing two liquids to mix in a tank where foam is produced. The tank is made airtight and sufficiently strong to permit of the foam being forced out by carbon dioxide under pressure, and the foam is conveyed to the fire by means of a line of hose. The exact nature of the liquids has not been disclosed, but one of them probably consists of a sodium-carbonate solution containing froth-forming ingredients such as glue or casein and the other an alum solution. The two on coming together generate carbon dioxide which produces froth. This froth is reported to be quite stiff and to shrink in volume but a comparatively small amount even after a period of half an hour.

A number of tests were conducted in the winter of 1912 in Germany; some of them on a considerable scale. In one case as much as 5 tons of crude naptha in a tank was involved, and in another an area of 1300 sq. ft. of burning tar was used. In all cases the results were reported satisfactory, the fires being extinguished in a short time.

The frothy mixture undoubtedly owes its efficiency to its blanketing action in settling upon the surface of the burning liquid, thus excluding the oxygen of the air, and to the fact that the bubbles of liquid contain carbon dioxide which upon bursting produce an atmosphere in which combustion cannot take place.

According to the latest reports the matter is still in an experimental stage, various details regarding the form of apparatus, most efficient pressure and design of nozzles being under consideration; but from what has already been done it would appear that the idea is a very promising one, and that this method of extinguishing fires in oils and volatile liquids will prove to be by far the most efficient of any that has as yet been suggested.

## Efficiency Exposition

The first national Efficiency Exposition and Conference will be held in the Grand Central Palace, April 4 to 11, inclusive, 1914. Its aim and purpose will be to give living expression to the increasing application of scientific methods to modern conditions.

The plan and scope of the show will include displays of efficiency appliances, methods and products in industrial, mechanical, governmental, educational and household fields. Not the least interesting feature of the show will be a series of mental and manual efficiency contests which will be staged along original lines and conferences and illustrated lectures on subjects of vital current interest.

The exposition will be held under the auspices of the Efficiency Society and in conjunction with the conferences of the Society and other scientific organizations.

Mr. William R. Wilcox, ex-chairman of the Public Service Commission, will, as president of the Efficiency Society, preside over the exposition which includes on its Advisory Committee such well-known names as F. H. Bethel, vice-president New York Telephone Company; James G. Cannon, president Fourth National Bank; Norman Hapgood, editor Harper's Weekly; William A. Marble, president Merchants' Association of New York; William A. Prendergast, comptroller City of New York; Lawson Purdy, president Department of Taxes and Assessments; Elbridge G. Snow, president Home Insurance Company; Arthur Williams, general inspector New York Edison Company; T. S. Williams, president Brooklyn Rapid Transit Company; Joseph French Johnson, dean New York University. Travis H. Whitney is the chairman of the Executive Committee.

**Leadville's metal production** for 1913 was valued at only $9,040,350, being about $2,000,000 less than for 1912. The total tonnage of ore mined was 453,360, of which 1/3 was zinc carbonate. The grand total value of Leadville's production to date is calculated locally as $406,451,061.

## Nitrates by Electrolysis of Peat

In an article in London *Electrical Review*, of December 19, 1913, Mr. Georges Dary describes a new scheme for utilizing peat deposits. The object is to produce from them nitrates by electrolysis. The inventor is Albert Nodon, the French electrical engineer, who has formerly become known by his work on the electrolytic aluminum valve. We quote the description of the process verbatim from the article of Mr. Dary.

"**M. Albert Nodon** has continued the research work of Mr. Müntz, and, as a result of long and exhaustive tests, has recently discovered an extremely economical process of extracting nitric acid and nitrates by treating peat deposits electrolytically. The process has recently been patented in the United Kingdom, to which country it is especially suited. By its means calcium nitrate, which is formed in considerable quantities and continuously in peat deposits can, in fact, be decomposed by electrolysis, the nitric acid passing to the anode, which is enclosed, while the lime accumulates about the cathode.

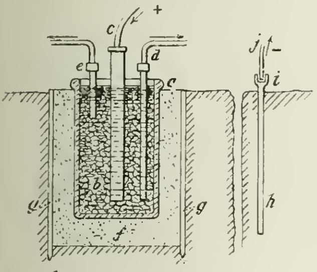


FIG. 1—ANODE AND CATHODE ELEMENTS

"The operation is effected automatically and continuously by means of a simple and cheap plant installed in the open air directly on the peat deposits, this accounting for the fact that the cost of production is practically restricted to that of the current consumed. The Nodon process, in fact, renders the usual heavy expenditure for the extraction, transport, and lixiviation of the peat entirely unnecessary, thus overcoming all the drawbacks which lead to the rejection of the Müntz scheme.

"The industrial arrangement of the Nodon method may be outlined as follows: Porous pots, filled with coke, which is utilized as the anode, and a weak solution of nitric acid, are installed at equal distances directly in the peat deposits. The nitric acid obtained by the electrolysis of the nitrates of the earth is gathered into tanks, while the lime resulting from the decomposition into calcium nitrate is collected by the cathodes, which latter consist of iron rods sunk into the deposits. Each anode element (Fig. 1) consists of a cylindrical porous pot *a*, of coarse pottery, rendered porous by the addition, before baking, of a paste of combustible dust. The pots which are 8 ft. 2 in. in height x 15¾ in. in diameter are sunk into holes dug in the peat, care being taken to tightly ram the earth below in order that there shall be no movement in the pots. Each of the latter is filled with washed coke, a large rod of graphite *c* being placed in the center of the same, its center being to convey to, and distribute, the positive current through the coke.

"It is very necessary that a perfect joint should be made between the graphite rod and the electric cable, as in batteries; with the view of ensuring this, the upper end of the rod is coppered, lead being cast between this and the end of the coppered conductor. Two glass tubes *d* and *e* project into the porous pot. The tube *d* extends practically to the bottom, while the other only penetrates just below the surface of the liquid. The object of the first tube is to draw off the water impregnated with nitric acid; while the tube *e* serves to replenish the pot with an amount of water equal to the liquid drawn off. Round each pot a circular space *f* is left, which is filled with calcium carbonate, or simply broken limestone. Stakes of tarred wood *g* separate the peat from the annular space, which forms a sort of cage for the limestone.

"The cathodes or negative poles *h* are of rough cast iron, and are of a square bar section, 8 ft. 2 in. in length. The upper end *i* is made of a cup shape, into which antimoniated lead is poured, in order to make a good connection with the conductor *j*. The whole is carefully tarred with the view of obviating any destructive action. The rods are located at a distance of approximately 4 in. from each other, and are connected to a common conductor *k* (Fig. 2). In this way a cathode of a large surface is secured.

"The porous pots are fixed at a distance of 3 ft. 3 in. from each other, the shortest space between any of the anodes and cathodes being 1 ft. 7½ in.

"As soon as the current is switched on, the following phenomena are observed: The ground of the peat bog may be regarded as an electrolyte, the specific resistance of which has been found equal to an average of 3 ohms per meter cube. This resistivity necessitates the employment of a pressure of 10 volts in order to secure sufficient current density. Under the action of this current nitric acid is produced at the anode, and lime at the cathode. . . .

"The nitric acid remains dissolved in the porous pots *a*; the solution is drawn off along the tubes *d*, and conveyed to a large storage tank by means of pumps *n*, water being admitted by tubes *e* to make up for the liquid extracted. The solution may be directly concentrated in sandstone evaporators, in order to produce pure nitric acid, for which there is a large demand. . . . The free acid is usually saturated with calcium carbonate. The solution is evaporated in boilers fired with dried peat, a calcium nitrate, similar to that supplied for agricultural purposes, being obtained by crystallization.

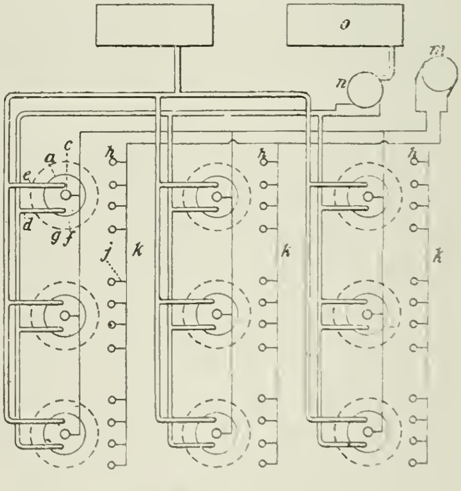

FIG. 2—ARRANGEMENT OF ELECTROLYTIC CELLS

"Peat is particularly adapted for the intensive production of pure nitrate; in fact, 2 per cent of its weight consists of nitrogen capable of being converted into fixed nitrogen under the simultaneous action of the nitric ferments, the oxygen of the air contained in the porous mass of peat, the hygrometric water and the heat developed by the passage of the electrical current.

"The flow of the current in the peat does not sensibly reduce the activity of the nitric ferments, so long as the density per unit of surface of electrodes is not too high.

"It is thought advisable to mix calcium carbonate with the peat, or, simply, a lime milk resulting from the lixiviation of the lime, which accumulates round the cathodes. Without this precaution the peat becomes impoverished as regards calcium, and the nitric ferments will quickly commence to act on the ground rendered acid by the free nitric acid. It is also well to prevent the development in the nitrate bed of ferments capable of paralyzing, as it were, the action of the nitric ferment; this can be done by distributing, by means of a pump, separately-prepared ferment solutions.

"All these operations can be effected quite economically by means of electrically operated pumps and distributing pipes fixed on the peat deposit.

"It has been found that the nitric ferment attains its maximum degree of activity at 25° C., while a continuously flowing current at a pressure of 10 volts is amply sufficient.

"A deposit of peat, having a depth of 6½ ft., and an average richness in nitrogen of 2 per cent, can produce between 800 and 900 tons of pure nitrates per year; while, according to the research work of M. Müntz, if the deposit is located near a town, and can be watered with liquid manure, it can be made to yield 6,000 tons of fixed nitrogen."

* * * * * * * * *

In the article an equation of the reaction is given which is clearly wrong. If the rection as claimed is really the electrolytic decomposition of calcium nitrate, the equation would be

$$Ca(NO_3)_2 + H_2O = 2HNO_3 + CaO$$

corresponding to a passage of 2 x 96,540 coulombs, if the symbols in the equation represent gram-molecules. Theoretically, 2 x 96,540 coulombs would, therefore, produce 126 grams $HNO_3$ or one amperehour 2.4 grams of $HNO_3$.

According to the article 1 amperehour gives 1 gram $HNO_3$ so that the current efficiency is 42 per cent.

Since according to the article the voltage per cell is 10 volts, 1 kw-hour produces 240 grams of $HNO_3$.

In Mr. Dary's article it is stated that for the most efficient operation 2500 porous pots and 36,000 iron rods are required per hectar (1 hectar = 2.47 acres) with a current density of 3.33 amperes per square meter of anode surface, or a current of 7.5 amperes per porous pot. Hence the current per hectar is 18,000 amperes. The production per 24 hours would, therefore, be 18,000 x 24 grams or 950 lbs. $HNO_3$ per hectar with a power consumption of 180 kw and an energy consumption of 4320 kw-hours.

In order to use energy supply at 100 volts, the peat deposit is divided into ten parallel trenches, electrically connected in series in such a way as to give a difference of potential at the two extremities of 100 volts, while using only 10 volts in each of the separate trenches.

Mr. Dary's article contains also a cost estimate, prepared by Mr. Nodon, for a plant for the electrolytic extraction of 100,000 tons of nitrates per year, but as it is only an estimate and based on European conditions, it is not reproduced here. The important figures claimed for the process are that the production of 1 kilogram of HNO requires 1000 ampere-hours and 10 kw-hours.

---

The National Association of Manufacturers of Medicinal Products will hold its annual convention on February 10th in New York City.

## Ductile Tungsten Patent

What must be considered as the fundamental patent for making ductile tungsten has now been issued. It is patent No. 1,082,933, granted on Dec. 30, 1913, to Dr. William D. Coolidge, of Schenectady, N. Y., and assigned to the General Electric Company. It relates to "Tungsten and Method of Making the Same for Use as Filaments of Incandescent Electric Lamps and for Other Purposes." The serial application in this case, filed June 19, 1912, was in part an extension of four prior applications, the earliest under date of July 2, 1906. The invention covered by this patent is the now well-known ductile tungsten for incandescent-lamp filaments and other uses, which was discovered in the research laboratory of the General Electric Company.

One of the interesting features of this patent is its history in the Patent Office. The primary examiner rejected the entire application on the ground of prior disclosures in British patents No. 21,513 of 1906, No. 3174 of 1907, No. 16,530 of 1907 and No. 24,179 of 1906. The examiner also held that certain claims should be divided, under another application, and that some of the other claims were duplicates in patentable effect. In a decision of the board of examiners-in-chief, filed on Nov. 15, 1913, the citation of the first three British patents named above was rejected on account of their having been filed subsequent to July 2, 1906, the earliest filing date in the Coolidge application. The members of the board also dismissed the other contentions of the primary examiner except as to duplication of claims, and the latter ruling was over-ruled by the examiner-in-chief, so that the original application was finally allowed intact.

Out of the thirty-four claims in the patent we quote the following:

"1. The process of producing tungsten having a fibrous structure which consists in repeatedly hot-working a crystalline body of tungsten until the crystalline structure is broken down and a fibrous structure developed.

"2. The process which consists in agglomerating tungsten powder, sintering the body thus formed, subjecting it to repeated hot-working, and continuing such hot-working until the body remains ductile when cold.

"8. The method of producing pliable tungsten wire for lamp filaments, which consists in first producing a body of tungsten in a sintered state and free from oxygen carbon and other impurities which would render the body unworkable mechanically and then subjecting this sintered and purified body to mechanical working many times repeated, with gradual reduction in diameter and elongation in length.

"12. The process which consists in reducing tungsten oxide to coarse tungsten powder, agglomerating said powder into a coherent porous body, heating said body to drive out impurities and sinter the body, and then subjecting the body to hot mechanical working.

"14. The process which consists in forming a body of tungsten powder containing additional material which will prevent coarse crystallization of the tungsten at high temperature, sintering the body and then subjecting it to hot mechanical working.

"22. The method of securing a ductile metal body without previous melting of the metal, which consists in producing a compact body of metal from divided metalliferous material, consolidating said body by heating to a temperature less than the melting temperature and such as to produce a body of metal non-ductile when cold, subjecting the body to repeated mechanical working while in a heated condition, and continuing the working until the body is ductile without the application of heat.

# The Kieselguhr Industry

BY PERCY A. BOECK

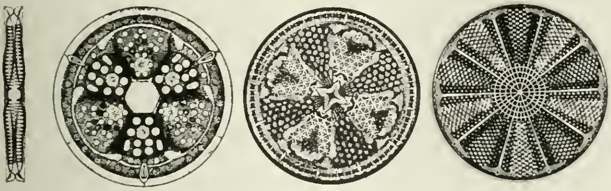
Many of the uses of kieselguhr, also known as diatomaceous earth, Tripoli, Sil-O-Cel, and sometimes as infusorial earth, have long been known. The ancient Greeks and Romans made the so-called "swimming brick" and the emperor Justinian, in 522 A.D., ordered the dome of the Hagia Sophia built of brick made of this material to lighten the weight of the structure.[1]

Since that time the applications of this material have increased in an almost endless variety of uses. It has not been until recently, however, that the use of kieselguhr in the industries has been developed systematically. This has been brought about to a great extent by the present-day keen competition, which has compelled closer attention to by-products and wastes, and by the ever-increasing tendency toward efficiency in industrial plants through the reduction of losses from all sources to the lowest possible point.

The available technical literature dealing with kieselguhr is not only limited in amount, but it is widely scattered and generally inaccessible. It is not the purpose of this article to attempt to enumerate or catalog all of its various uses, but rather to summarize and discuss briefly its nature and properties in such a way as to bring out the principal applications of this important, and, in this country, somewhat neglected mineral.

## Formation

Kieselguhr deposits are formed by the precipitation of the remains of bacillariæ or diatoms, one of the groups of flowerless aquatic plants of the species "algæ," which occur almost universally in all waters from arctic to torrid, fresh or salt, still or running. There are innumerable varieties of diatoms, over 4000 distinct forms having been classified and described. These vary greatly in size from that of a head of a pin easily visible to the naked eye, down to such a minute size as to be revealed only by the highest power of the microscope.



FIGS. 1 TO 4.—DIATOMS LARGELY MAGNIFIED

The silica shell or casing of these plants is secreted by the assimilation of inorganic substances in solution in the water about them through the agency of sunlight in conjunction with the chlorophyl masses which compose the bodies of the plants. Diatoms multiply with great rapidity and float about in the water or on its surface while living. When the organism dies it sinks to the bottom where the countless myriads of shells accumulate, carrying down with them varying amounts of undecomposed organic matter of which a part remains even centuries after.

The valves or shells of which there are always two exact counterparts are in many instances elaborately carved and ornamented with the most intricate and delicate designs of marvellous variety, which make these plants the most ornate of all living organisms, and has properly earned for them the title of "Jewels of the Plant World."[2] A magnification of from 200 to 500 diameters is usually sufficient to reveal the finer and more delicate tracings on these shells, but occasionally much higher magnifications are necessary. The microphotographs shown in Figs. 1 to 4 give some idea of the variety and nature of diatoms in American samples of kieselguhr.

## Composition of Kieselguhr

The accumulations of these diatomaceous shells is in most deposits contaminated by interposed impurities which also settle to the bottom of bodies of water or are carried along with the sinking diatoms. This may be in the form of diatomaceous ooze, silt, clay, sand or volcanic ash and other inorganic materials from which it is commercially impossible to separate the diatoms. In a few deposits such as that which is found near Lompoc, California, the diatoms occur in enormous beds of unusually pure and uncontaminated kieselguhr. Analysis of several materials from this deposit show the following composition on the moisture free basis:

Sample (1) Very light-weight pure white kieselguhr.
(2) Light-weight brownish kieselguhr
(3) Compact diatomaceous shale.

| | (1) | (2) | (3) |
|---|---|---|---|
| Silica ($SiO_2$) | 88.78% | 85.28% | 94.59% |
| Alumina ($Al_2O_3$) | 2.68 | 5.35 | 1.87 |
| Iron oxide ($FeO$) | trace | 1.12 | .76 |
| Titanium oxide ($TiO_2$) | 0.10 | 0.21 | 0.10 |
| Lime ($CaO$) | 1.61 | 1.12 | .83 |
| Magnesia ($MgO$) | 1.30 | 1.30 | trace |
| Loss on ignition | 5.54 | 5.57 | 2.22 |
| Color | White | Ivory | White |
| Color after ignition | White | Pink | White |

In its natural state kieselguhr contains from 25 to 45 per cent of moisture which is expelled at 100 deg. C., and is pure white to brownish, very light weight, soft, easily abraded material. The condition of the silica, its principal constituent, is one of the characteristic properties, it being in the amorphous or opaline state carrying ordinarily from 5 to 10 per cent of combined water. In many cases this silica has been erroneously reported by some of the older writers as "colloidal silica," this term being used synonymously with amorphous silica, due in all probability to the vague understanding of the term. This, however, must not be taken to indicate that kieselguhr has no colloidal properties, for as a matter of fact these properties are strongly marked but variable, similarly as in a great many clays and show a decided absorption with malachite green oxalate. In certain cases a higher absorption of this dye is obtained by kieselguhr than on samples of Fuller's Earth, in which the bleaching or clarifying action has been shown to be due to a large extent to the physical condition of absorption and dependent on the colloidal content of the earth.[3] The condition of the silica in kieselguhr is further indicated by the fact that it is easily decomposed by means of hydrofluoric acid, is soluble in solutions of sodium carbonate of all strengths and yields water on heating in a closed tube. The specific gravity of kieselguhr is approximately 2.1 to 2.2 at 25 deg. C.; indicating that it is amorphous silica, which is usually taken as 1.9 to 2.3.

## Lompoc Deposit

The geology of this deposit has been studied extensively by Mr. W. B. Schilling, E. M., who gives the following description: The deposits of kieselguhr of Northern Santa Barbara county, California, are largest and best of any known deposits and of great importance because of their pure state and workable condition. In the region immediately south of Lompoc there occurs a deposit of literally mountains of this material owned privately in one tract almost chemically pure and covering an area of many square miles. Fig. 5 shows a mountain of kieselguhr at Lompoc, California.

[2] Mann: Smithsonian Miscell. Coll., v. 48.

[3] C. L. Parsons: Mineral Technology, Bureau of Mines, Bul. 71

This deposit occurs in the Monterey or Middle Miocene formation. All gradations from the soft diatomaceous material to the hardest of black flints may be found, thus indicating the extreme localization of the conditions that produced the harder varieties from the unaltered deposits. In some places the material is in great soft masses in which the bedding cannot be recognized except by the characteristics weathering into flakey layers parallel with the original bedding planes. Everywhere else it is more compact and in thin beds, ranging from one-half an inch to two and three inches in thickness, or in massive beds. The beds are tilted and in conformity with the much disturbed hard bed of flinty shale of the lower portion of the Monterey formation, of which the whole series is a part. The least known thickness of this deposit in a pure state is 700 feet.

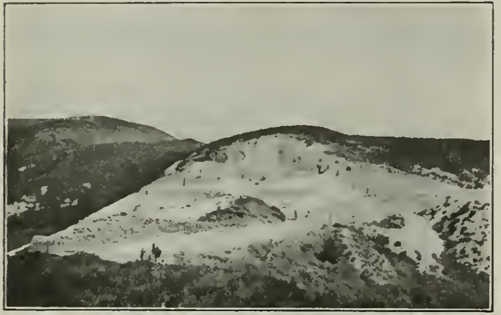

FIG. 5—A MOUNTAIN OF KIESELGUHR AT LOMPOC, CAL.

## Mining and Milling

The mining or quarrying of this material is carried on by means of an open face workings where the kieselguhr is taken up in huge blocks. (See Figs. 6 and 7.) This operation is made easier where transverse seams occur in the strata, due to local folding. Where these seams do not occur it becomes necessary to loosen the kieselguhr slightly by means of powder before the blocks can be removed from the quarry face.

Owing to the peculiar physical structure of the kieselguhr it has for ages been absorbing the surface waters and it is necessary that the material be split into convenient blocks for piling and drying, as shown in Fig. 8. The amount of absorbed water is about 25 to 45 per cent by weight and owing to the winds and dryness of the atmosphere of Southern California, this amount is reduced to about 5 per cent by natural air drying within forty to fifty days.

After drying the kieselguhr is hauled by means of motor truck to the reduction works where it is reduced and transferred by means of a pneumatic system to the different warehouses. It is likewise drawn to the finishing mill from the warehouse by this means and ground and blown into the several grades used commercially. When blocks are required the material is transported in its natural state direct from the quarry, sawed into the sizes required for building purposes and dried before shipment. Waste material too fine to be dried is utilized in the making of brick, tile and other refractory materials of light weight.

## Properties of Kieselguhr

The general characteristics which make kieselguhr of great commercial importance for various purposes may be outlined as follows:

- I. *Physical.*
  - (a) Form.
    - (1) Enclosed air cells.
    - (2) Large exposed surface of cells.
    - (3) Fine state of division.
    - (4) Sharpness of cells.
    - (5) Weakness or low compressive strength of cells.
  - (b) Refractory nature.
  - (c) Presence of large amount of colloidal material.
  - (d) White color.
- II. *Chemical.*
  - (e) Siliceous or inorganic nature.
  - (f) Easy solubility in alkalies.
  - (g) Insolubility in acid or neutral solutions.

The detailed description of these properties will be taken up in connection with the most important of the applications which depend on the specific property under consideration.

## I. Physical Properties

### 1. ENCLOSED AIR CELLS

The highly porous condition of the diatoms is shown in the microphotographs of Figs. 1 to 4; they, however, do not indicate the extent of this most important property as well as the statement of the amount of solid material in a unit volume.

*Light Weight.*—The apparent specific gravity of the raw blocks, as they are mined, after drying, varies considerably, depending upon the amount of material transformation which has taken place at the particular deposit. The apparent density of the dry, crude blocks is about 0.45 equivalent to 28 pounds per cubic foot, while that of the pulverized material, made from them, when loosely packed, has an apparent density as low as 0.13, equivalent to 8 pounds per cubic foot, which can be doubled with packing. In other words, in one cubic foot of the loose material there is but 0.058 of a cubic foot or 100.2 cubic inches of silica having a density of 2.2.

FIG. 6.—AN OPEN KIESELGUHR QUARRY FACE

*Filler or Diluent.*—This unusual bulkiness and light weight makes this material an excellent filler or addition agent for increasing the volume of materials largely without appreciably increasing their weight, and has found extensive application in the manufacture of light-weight tile, brick, partition-tile and as a filler for almost any character of bonding material. As an addition to portland cement it has been found that the strength is increased particularly on aging and completely preventing the destructive action of sea water

(Feret test for durability) for more than two years.[4]

*Thermal Insulator.*—The microscopic voids or "dead air" cells in and between the diatoms form an excellent natural barrier to the passage of heat making it the most effective inorganic thermal insulator known. This application is one of the oldest and most important of the uses of this material. The thermal conductivity of the dry natural kieselguhr block, loosely packed kieselguhr, and of the kieselguhr insulating brick and firebrick have been found to be as given in table 1, the values for the conductivity *k* being given in gram-calorie seconds, i. e., the transfer of heat between opposite faces of a centimeter cube at a rate of one gram-calorie per second per each degree of centigrade difference in temperature of the faces at the temperatures indicated.

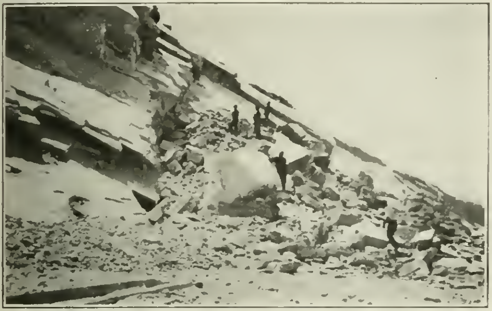

FIG. 7.—QUARRYING KIESELGUHR IN CALIFORNIA

This most important property of kieselguhr has been used extensively for the production of fireproof and incombustible insulator in the form of loose powder, solid natural blocks, burned insulating brick and tile, pipe covering, etc., for both high temperatures in ovens, cookers, furnaces, annealing pits, boilers, evaporators, stills and for low temperatures in cold storage and refrigeration plants, icehouses, iceboxes, coolers and similar purposes. It has the advantages over the organic insulating materials, some of which have a somewhat higher thermal resistivity in that it is unaffected by extreme heat or cold, and is not subject to decomposition, decay or any physical change with time.

*Sound Deadener.*—On account of the same physical properties this material has found extensive use as a "deadener" or sound proofing material in and between the walls and floors of apartment houses, office buildings, school houses, booths, hospitals, etc.

*Absorbent.*—The high porosity of kieselguhr has further brought about its use as an absorbing medium for a variety of materials wherever it is desirable to give the properties of a solid to a liquid or semi-solid material; or in the recovery of waste liquors or by-products not readily available or handled with facility in a liquid form. As an absorbent the uses of kieselguhr are too numerous and varied to mention. Chief among them are fertilizing materials and corrosive liquids. Pulverized kieselguhr absorbs from 150 to 200 per cent. of its weight of water without changing its form. It has also been used for an absorbent or vehicle for liquid disinfectants which are evolved slowly rendering them active for a long period of time.

*Filter.*—For the filtration of liquids the porosity of kieselguhr plays an important part, not only in mechanically retaining the finest suspended matter in the solution, but also aiding materially in keeping the filtering medium and deposited material in an open, porous state, preventing sliming and clogging, producing open, easily handled filter cakes of considerably increased filtering capacity. In the sugar industry both in Europe and in this country, kieselguhr finds almost universal application.

For the filtration of oils, excellent results have been obtained in certain cases by substituting kieselguhr for Fuller's Earth wholly or in part. This is due, in all probability, to a large extent to the high percentage of colloidal material in kieselguhr, as well as to its open and porous structure. Filters of bonded burned kieselguhr have been in use for many years, both abroad, where they originated, and in this country.

In a report on these filters Dr. Martin Kuchner states that filters of this material are four times more efficient than any similar filter as to quality and quantity of filtrate. In a test, bacteria appeared in the filtrate after three days in an ordinary filter, while in the case of kieselguhr no bacteria were found in the filtrate, even after six days of continuous operation without cleaning.[5] These filters are now used exclusively in the preparation of serum, toxines and products of a similar nature. They have lately also come into extended use in the removal of moulds and ferments from beers and fermented liquors.

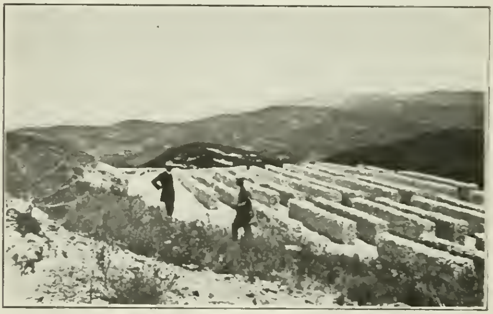

FIG. 8.—KIESELGUHR CORDED OUT TO DRY

### 2. LARGE EXPOSED SURFACE OF CELLS

The large surface presented by the kieselguhr diatoms has brought about its use as a carrier for the active material in several catalizing processes, notably in the hydrogenation of unsaturated oils, in which process, for example, cottonseed or other vegetable oils are converted into the consistency of lard by the addition of less than 1 per cent. of hydrogen to the oil, which reaction is brought about by means of a catalizer, such as nickel oxide deposited on kieselguhr as a carrier. In

TABLE 1—THERMAL CONDUCTIVITY OF KIESELGUHR PRODUCTS in Gram-Calorie Seconds at Various Temperatures

| | Apparent density | 200° C. | 300 | 400 | 500 | 600 | 700 | 800 |
|---|---|---|---|---|---|---|---|---|
| Natural kieselguhr block (dried) | 0.53 | 0.000227 | 0.000259 | 0.000276 | 0.000287 | 0.000298 | 0.000308 | 0.000315 |
| Pulverized kieselguhr (loosely packed) | 0.12 | 0.000127 | 0.000187 | 0.000248 | 0.000294 | 0.000332 | 0.000364 | 0.000397 |
| Kieselguhr insulating brick (burned) | 0.75 | ....... | 0.000448 | 0.000480 | 0.000510 | 0.000542 | 0.000573 | 0.000604 |
| Kieselguhr firebrick (burned) | 1.05 | 0.000371 | 0.000472 | 0.000553 | 0.000623 | 0.000683 | 0.000738 | 0.000791 |

---

[4] Poulson: Trans. Internat. Assn. Test Materials, 1912, et seq.

[5] Zeit. fur Hygiene, 14,299 (1893)

this case the large area of the carrier adds considerably to the activity of the catalizer and also aids in the filtration and removal of suspended matter from the oil after the reaction is completed.[6]

### 3. FINE STATE OF DIVISION

The natural fineness and uniformity of the particles which go to make up kieselguhr and the ease with which it can be reduced without destroying the cell structure make it useful for many purposes, among which are: Polishing and dusting powders and in many industrial and pharmaceutical lines.

### 4 AND 5. SHARPNESS AND WEAKNESS OF CELLS

The angular nature of the flinty skeletons of the diatoms give kieselguhr an abrasive power which is taken advantage of in the finer grades of polishing and cleaning materials, where a mild abrasive is required. The fineness, together with the angularity, weakness and low compressive strength of the diatoms produce a material which is unsurpassed for polishing and burnishing objects without danger of scratching the surface of the softest metal.

It has been used extensively for metal polish, soaps and for polishing metallic specimens for microscopic examination, dental powders, etc. The above properties are also taken advantage of in producing friction surfaces in the manufacture of safety match surfaces, match heads and similar lines.

### b. REFRACTORY NATURE

As the diatom consist chiefly of silica, a material which is in itself of a refractory nature,[7] this valuable characteristic as a whole is imparted to kieselguhr. The melting point of natural powdered kieselguhr has been reported by the Bureau of Standards to be 1610 deg. C. (2930 deg. F.), and that of a lightweight diatomaceous shale 1,750 deg. C. (3,182 deg. F.), indicating its highly refractory nature. This feature, together with its low thermal conductivity, opens up a wide field for its use in the ceramic industries for the production of lightweight brick and tile for insulating and refractory purposes. Owing to the low apparent density of the pulverized kieselguhr it has found extensive application for fire protection in buildings as a light fireproof wall filler. On account of its smothering effect caused by the exclusion of oxygen from the vicinity of the flame, it is also used as a fireproofing and insulating material in safes, ovens, fireless cookers, electric fuse protectors, etc.

### c. COLLOIDAL CONDITION

The bleaching and decolorizing properties of certain clays, notably in the case of Fuller's Earth, has long been known to be due to the presence of colloidal matter.[8] Recent work on kieselguhr has shown that it carries a large amount of colloidal material, as is indicated by its absorption of certain basic dyes. In certain cases this absorption has been found to be as much as 20 per cent. higher than in the case of a high-grade Fuller's Earth, making it of particular value in the treatment and filtration of a number of materials which were formerly carried out only with great difficulty.

### d. WHITE COLOR

The white color of kieselguhr naturally depends upon the small amount of impurities in the material and upon the freedom from deleterious sediments which settle along with the diatoms in many deposits. When of a high degree of purity the pure white color imparts valuable properties to kieselguhr in pharmaceutical applications being used in the preparation of many drugs and dentifrices in which the essential qualities are purity.

## II. Chemical Properties

### e. INORGANIC OR SILICEOUS COMPOSITION

As has been shown above, the chief constituent of diatomaceous remains is silica, which, under certain conditions, is found in a high degree of purity in a form which is readily available, thus forming an ideal source of pure silica for a variety of purposes. It has been used as an ingredient in the compounding of glazes, fluxes and bodies of a siliceous nature. The specific heat of kieselguhr has been determined by Becker to be 0.2089.[9]

### f. SOLUBILITY IN ALKALIES

One characteristic of the silica contained in kieselguhr is the ease with which it reacts and combines with alkalies and alkaline salts, making it a convenient form of silica for the manufacture of silicate of soda or water glass, ultramarine and other siliceous products.

### g. INSOLUBILITY IN ACID OR NEUTRAL SOLUTION

Kieselguhr is not affected by the action of acids (except hydrofluoric) or netural solutions, which feature makes it suitable for the filtration, absorption or transportation of these bodies without contaminating them.

## Testing Kieselguhr

In industrial work it is essential in order to obtain the best results that the kieselguhr which is best adapted to the particular requirements be used. In order that this may properly be determined, it is advisable to apply certain chemical, physical and mechanical tests, which will be outlined. While it is unnecessary in a great many cases to carry out all of these tests in detail, it will be found that they give the general character and adaptability of the material for the purposes intended. For instance, for filtration of materials, the apparent density, fineness and behavior of the kieselguhr in solution will enable a far better valuation of the material to be made than chemical analysis. For ceramic purposes the analysis showing the amount and nature of the fluxes present would be of the greatest importance. In short, the testing of this material should be carried out with an idea of determining the physical properties which have the greatest bearing on the manner in which the material is to be used.

*Sampling.*—On account of the relatively small percentage of material other than amorphous silica present in kieselguhr, and the large surface and porous nature of the material, it is essential that the sampling be done with great care in order that a representative sample may be obtained. For accurate work it is advisable that all samples be weighed out at the same time and the percentage of moisture determined in one of them, and also that the weighing be carried out as rapidly as possible on account of the change in weight due to the loss or absorption of moisture.

*Color.*—The color of kieselguhr as it is received should be determined on a sample of approximately 150 mesh, both dry and moistened with water. Some information can also be obtained by comparing the original color of kieselguhr with that of ignited kieselguhr which has been heated above 1,000 deg. C. under oxidizing conditions. The color of the last-mentioned sample will be of value in determining the approximate percentage of iron oxide in the material and may be made upon the sample from the "Loss on Ignition," as will be outlined in the analysis of kieselguhr.

---

[7] Knolt: Technologic Paper 10 of the Bureau of Standards reports pure silica flows distinctly at 1750° C.

[8] Parsons: Fuller's Earth, Bureau of Mines Bulletin.

[9] Johresber: Chem. Tech. (1876), c. 22, p. 481.

*Apparent Density.*—In the case of pulverized kieselguhr a tared vessel is filled loosely with the material and the excess scraped off of the top by means of a straight-edge. The weight of kieselguhr divided by the weight of an equal volume of water gives the apparent density. In the case of blocks or bricks made of kieselguhr, this value is obtained readily by measuring and weighing the sample.

The apparent density is one of the most valuable and most readily determined of the physical properties of kieselguhr, and forms an excellent criterion for the approximate comparative efficiency of the product for many purposes.

*Fineness of Grain.*—A weighed sample is washed through the proper size screen with a fine jet of water, and the residue dried, weighed and the result expressed in percentage loss through the various sizes.

*Character of Grain.*—The shape and general character of the kieselguhr cells and the approximate amount of inactive or non-cellular material present may be readily determined by means of the microscope. The source of the material may often be determined by a microscopical examination.

*Absorption.*—A dried five-gram sample of kieselguhr is allowed to absorb a measured quantity of water from a burette until continued stirring fails to produce a pulverulent mass. The absorption coefficient is expressed in terms of cubic centimeters of water absorbed per gram of dried sample. The stirring should be done in a manner least destructive to the frail cells, grinding and crushing being avoided.

*Chemical Analysis.*—One-half gram sample is weighed in a platinum crucible, heated to redness to drive off organic matter, cooled, moistened with small amount of distilled water, about four drops of dilute sulphuric acid and one cubic centimeter of hydrofluoric acid added. Heat on a sand bath to fumes, and repeat the operation until decomposition is complete, after which the crucible is ignited strongly until constant in weight. The loss consists of moisture, organic matter, combined water and silica. Of these the moisture is determined on a separate sample at 105 deg. C. and the organic matter and combined water are determined on the same sample as "Loss on Ignition" by continued strong heating until constant weight is obtained. These values are then deducted from the complete loss, giving the silica content of the sample. The residue from the hydrofluoric acid treatment is fused with sodium potassium carbonates, dissolved in diluted hydrochloric acid, oxidized with bromine water and the hydroxides precipitated by means of ammonia which are filtered off, ignited and weighed. In the precipitate the iron, alumina and titanium oxides are determined by any of the well-known methods and the lime and magnesia determined in the filtrate.

### Kieselguhr Products

In selecting the most suitable kieselguhr product for use it is quite often possible that a number of the properties desired can be obtained from several of the products, and particular care should be taken to select the one which has the greatest applicability to the problem in hand.

*Natural Kieselguhr Blocks.*—Sawed natural kieselguhr blocks, when dry, are light, weighing approximately twenty-eight to thirty-five pounds per cubic foot. They are fairly strong, having a crushing strength of 400 pounds per square inch, and have an exceptionally high insulating value, as shown in Table I. Their melting point is 1,610 deg. C. (2,930 deg. F.), and are unaffected up to temperatures of a red heat, except for slight shrinkage. They can be sawed to almost any size or shape, and offer an ideal and highly efficient material for insulation of moderately heated bodies and for cold storage work. For very high temperatures, however, they have the disadvantage of shrinking and spalling.

*Pulverized Kieselguhr.*—The natural kieselguhr when reduced in a manner which does not destroy the structure of the diatoms is ordinarily supplied in many grades of fineness and weight suitable for any of the uses to which this material may be applied. The weight per cubic foot varies between eight and twelve pounds, according to the grade and state of division. The color of the various grades runs from pure white to light brown, depending on the percentage of impurities present. The silica content ordinarily runs from 80 to 90 per cent. on the dry sample. The material has a very high thermal and sound insulating value, and is used as a filler for a variety of purposes, as indicated above.

*Lightweight Kieselguhr Insulating Brick.*—When pulverized kieselguhr is treated and burned under proper conditions a lightweight brick is produced which has a very high insulating value, which is fairly refractory, and sufficiently strong to withstand considerable handling and transportation. In preparing this brick it is essential that the kieselguhr be treated in such a way as to retain its natural insulating properties as far as possible. It contains approximately 95 per cent. silica, has an apparent density of 0.70 or less and an approximate weight of 45 lbs. per cubic foot. A regular size building brick weighs approximately $1\frac{3}{4}$ to 2 lbs. While this brick is not adapted to highly refractory use on account of its shrinkage at high temperature, it can be used for insulating purposes up to a red heat without damage. On account of the fine grained texture of this brick, however, it is advisable to protect it from extremely sudden changes in temperatures. The compressive strength of this brick is about 500 lbs. per square inch. It is used principally as an insulating backing for more refractory brick.

*Kieselguhr Firebrick.*—Firebrick made of kieselguhr flint are acid, highly refractory brick of a much higher insulating property than any firebrick now on the market. They are used for building and lining high-temperature furnaces, kilns, boiler setting and general metallurgical work where a lightweight non-conducting, refractory brick is required. The apparent density of this brick is approximately 1.00; a standard size firebrick weighing about 3 to $3\frac{1}{2}$ lbs. The Bureau of Standards reports the melting point of this firebrick to be 1,650 deg. C. (3,002 deg. F.). The thermal conductivity has been found to be in accordance with the table given above. The crushing strength of this brick is approximately 1,200 lbs. per square inch.

Research Laboratory, Kieselguhr Company of America.
Los Angeles, California.

## Manganese Bronze

BY W. M. CORSE AND V. SKILLMAN

Prior to the final quarter of the last century it was well known that the addition of small amounts of iron to copper and its alloys had a decided hardening and strengthening effect. Its introduction resulted at the same time in producing some less desirable qualities, as, for instance, a decreased ductility.

In the constant search for something better, the introduction of manganese in place of iron was tried. Cupro-manganese was prepared by reducing pyrolusite or a purer form of manganese dioxide in the presence of copper. This alloy was then employed to introduce small amounts of manganese into brasses and bronzes. Some benefit resulted and the manganese brasses and bronzes met with favor for some time. The manganese acted as a deoxidizing agent, much as the later perfected introduction of phosphorus in bronzes does. There do not seem to be on record the results of any experiments which would give the comparative value of iron and manganese when introduced separately into brasses and bronzes.

It remained for P. M. Parsons, of London, England, to add both iron and manganese. As a result he was granted British Patent 482, February 7, 1876, for his invention. A sentence from the patent reads: "Alloys of copper and tin or zinc, or both, may be rendered more homogeneous, closer in texture, harder and stronger by adding thereto a proportion of ferro-manganese, spiegeleisen, or other carburet of iron containing manganese." It should be noted that his patent was simply for the introduction of iron and manganese into alloys of copper and tin or zinc, or both. No mention was made of any particular alloy at all similar to the special brass which is now quite universally termed manganese bronze. The addition of iron and manganese to a metal containing 90% of copper and 10% of tin (gun metal) which is a true bronze was mentioned.

In the United States a patent No. 206604,1878, which was a duplicate of the British patent, was granted to Mr. Parsons. These patent rights were controlled by the Manganese Brass & Bronze Company, Ltd., of London, England. They proceeded to manufacture several different metals containing iron and manganese as specified. The alloys ranged from those containing zinc much in excess of tin to others composed of practically copper and tin alone.

It was soon discovered that the manganese brasses or high zinc alloys were entirely unsuited for sand castings and could only be employed successfully for casting in metal molds. It was not long before they were discarded almost completely in favor of the manganese bronze, composed of copper, tin and manganese, which gained some popularity. The first castings, therefore, of propellers and the like, which were described as being made of manganese bronze, were cast from true copper-tin bronzes.

These bronzes were not subject to the same casting limitations as the brasses. They could be readily handled in sand, but on account of the greater cost of tin as compared with zinc they were more expensive than the brasses. The latter in the form of forgings, rods, wire, etc., had been shown to possess such desirable properties in regard to strength, ductility and the like that there seemed to be little doubt of their value in the form of castings if such could be successfully made in sand. This was later made possible by adding a small amount of aluminum to the manganese brass, and here begins the history of the now well known, but wrongly named, manganese bronze casting.

In 1888 Mr. Parsons was granted a second British patent (No. 11512, August 9, 1888) covering the addition of aluminum to the class of alloys mentioned in his previous patent. For some reason he seems to have failed to take out a duplicate United States patent for this. United States Patent No. 415832 was granted to A. H. Cowles, however, for the same idea.

With this knowledge at hand it was now possible to make sand castings from a cheap brass containing as much as 40 to 45%, zinc, which would have physical properties equal, or even superior, to castings made from the more costly bronze. Probably on account of the bronze-like properties of the newly discovered brass, a confusion in names resulted and until comparatively recent times, manganese bronze was used to describe both the tin and zinc alloys of the type under consideration. This also accounts for the great discrepancy for a time in statements regarding the physical properties of manganese bronze.

While progress was being made in Europe in the incorporation of iron and manganese in brasses and bronzes, the metallurgists of this country were not dormant. The effect of ferro-cyanide, ferro-manganese, manganese oxide and the like was being studied. A brass called "Vesuvius Metal," which contained both iron and manganese had been developed. It contained no aluminium and was found to be unsuited for sand casting. Shortly after, another brass called "Tubal Bronze" was evolved which was followed by Consol Metal and numerous other brasses of the same general character.

About 1893 the Manganese Bronze and Brass Company, holders of Parson's patent rights, licensed the rights for making Parson's manganese bronze in the United States. Since then many companies have undertaken the manufacture of this important alloy. There need now be very little uncertainty as to what is meant by manganese bronze. Practically all the best brands upon the market at the present time fall approximately within the chemical specification adopted by the American Society for Testing Materials which calls for an alloy containing 55 to 60% copper and 40 to 45% zinc with small amounts of iron, tin, manganese, aluminium, etc.

It will be noted that the alloy now recognized as a manganese bronze is in reality nothing more than a special high-zinc brass. The presence, however, of the metals other than copper and zinc is what places this highly valuable alloy in a class quite by itself. At the present time it is the principal non-ferrous alloy employed in the form of castings to any extent, as a substitute for steel. Its valuable physical properties are quite dependent upon the proper proportioning and alloying of the elements present in small amounts.

Commercially, there are two grades of manganese bronze now manufactured. One which is used for rolling and drawing is very similar to the old manganese brass and contains no aluminium. Its copper content is also slightly higher than the other grade which is used for sand castings. The latter contains aluminium. They are both manufactured in about the same way and a description of the method used in making material for sand castings would explain the process.

The first step in the manufacture is the preparation of the hardening or "steel alloy." This is composed of the iron, manganese, and tin which is to go into the mixture. Ferro-manganese is usually employed and the additional iron necessary is introduced in the form of wrought iron. Straits, or some other good grade of tin should be used.

The formula mostly followed is, approximately,

| | |
|---|---|
| 80% Ferro-manganese | 56.3% |
| Wrought iron | 12.5% |
| Tin | 31.2% |

By introducing the tin into this alloy the melting point is so much lowered that the otherwise difficultly melted ingredients are readily dissolved in the copper when the final bronze is made.

After a stock of hardener has been prepared the alloying of the bronze is proceeded with. The mixture commonly employed is as follows:

| | |
|---|---|
| Copper ingot | 55.0% |
| Zinc | 42.0% |
| Hardener | 2.5% |
| Aluminium | 0.5% |

A portion of the copper is melted and after being brought to a good heat the hardening alloy is added. This must be thoroughly stirred in and heating continued until it is entirely melted and alloyed. The aluminium is then added which causes a further increase in temperature, which insures the melting of the last traces of hardener. The remainder of the copper is then added and allowed to melt, after which the zinc is added. A good grade of zinc is necessary, as the lead present as an impurity in the poorer grades is very detrimental in the finished bronze. The whole is then thoroughly stirred, brought to the proper temperature and poured.

It is usual practice to cast the newly formed alloy into ingots and to remelt them to make castings.

If the preceding formulæ are followed a bronze should be produced which would fall within the specifications issued by the United States Navy Department, January 20, 1912, and which call for manganese bronze containing

Copper, 56 to 58 per cent.
Zinc, 40 to 42 per cent.
Tin, not to exceed 1 per cent.
Aluminium, not to exceed 0.5 per cent.
Lead, not to exceed 0.10 per cent.
Manganese, not to exceed 0.3 per cent.

As regards the physical properties of the above alloy, a test specimen properly cast in sand should give well over 70,000 pounds ultimate tensile strength per square inch, and at least 20% elongation in two inches. Some specifications also call for a minimum elastic limit per square inch, and a minimum reduction of area. The values given for these have been shown to depend to such an extent upon the "personal equation" of the operator conducting the test and upon the apparatus with which he is working that it would appear preferable to leave them out of future specifications.

Bronzes of various strengths and ductility can be produced by varying the percentages of copper and zinc and of hardener used in making the alloy. If more elongation is desired, less of the hardening alloy is added. A greater quantity of the latter would produce a stronger and harder alloy, but one with less reduction of area and elongation.

The percentage of the ingredients used in making the hardening alloy may also be varied slightly, as each plays a particular part. The iron, which is most important, increases the strength and raises the yield point of the bronze. The tin also increases the strength, but if present in more than a certain amount, also causes brittleness. The manganese acts as a deoxidizer and is considered by some as a carrier of the iron. Its presence causes the iron to alloy more easily at least. If sufficiently large amounts are added it has a strengthening and hardening effect similar to iron, but not as pronounced.

In making castings from manganese bronze when the alloy has been successfully prepared, the goal is still only partly won. It is generally conceded by founders that this alloy is one of the most difficult of the non-ferrous mixtures for the uninitiated to properly handle. The metal may be quite ruined by allowing it to remain in the furnace and overheat after it has been properly made. As a result of the high zinc content, its melting point is comparatively low, lying between 1400° and 1500° F., and therefore overheating or "burning" easily happens.

Chemical control is a necessity in handling this alloy if rigid specifications are to be continuously met.

The approximate production in the United States of this alloy is 1500 tons annually.

Buffalo, N. Y.

---

**Tin in the form of cassiterite** is found with gold in the gravel on Sullivan Creek, near Rampart, Alaska. In the richest spots the gravel will yield as much as half a pound of tin to the pan. This is equivalent to a value of about $18 per yard. Stream tin is worked in the York district where the gravel has a value of only $9 per yard.

# Federal-State Controversy Over Radium-Bearing Lands in Colorado and Utah

*[Editorial Correspondence]*

Interest in radium-bearing minerals in the United States has grown rapidly in the last year. Twelve months ago radium was considered largely of academic importance, but to-day the potential value of a genuine radium industry in this country is recognized, not only by those whose foresight has given the matter its present prominence, but also by technical men whose interests have been centered in other branches of mining and metallurgy. Federal and state officials are concerned as to the disposition of land containing radium-bearing minerals, and a strong sentiment is developing in favor of some means of securing for our country an adequate supply of radium from our own ores.

Colorado and Utah are the states most concerned. The deposits of radium-bearing minerals in these states have received careful attention from the Bureau of Mines, which has given welcome publicity to the whole matter of uranium, radium and vanadium in a preliminary report recently issued as *Bulletin* 70.[1] "The United States possesses unique deposits in these (Colorado and Utah) carnotite ores. They constitute at present the largest known supply of radium-bearing minerals in the world. With the exception of the ore mined and utilized by two firms, practically every pound is shipped abroad. Up to the present very little interest has been shown by Americans in these deposits, which may not be duplicated as to quantity in any part of the world. The only other large deposits of uranium-bearing ores known are those of Austria. They are considered of such importance that the Austrian government has taken entire charge of them. The output from the carnotite fields of this country is much larger than that from the Austrian mines and is likely to continue larger for some time to come, but the ore should be mined with minimum waste, and the industry should yield a maximum profit to this country."

In the light of these facts it is not surprising that our deposits have attracted the attention of European buyers, and that scientists and government officials in this country should become interested in exploiting them in such a way as to produce first an adequate supply of radium for domestic use, without undue prejudice to the needs of foreign countries. The private organization of the National Radium Institute in this country was a step in that direction.

## The Controversy

A proposal on the part of the government to withdraw the Colorado-Utah carnotite deposits from private entry has precipitated a storm of criticism, particularly in Denver, against a further exercise of federal conservation of the states' resources. Colorado's commissioner of mines has been particularly active in creating a sentiment of opposition to such an action. It is argued that federal interference at this time, when the mining and treatment of carnotite promises to become an important item in the state's mineral industry, would be most unfortunate; that it will retard the development of the state; deter further prospecting; limit the employment of miners and freighters, and generally act as a bar to progress.

Another argument by the state is that the greater portion of the carnotite produced is now used by domestic companies, and that a needless cry is being raised against exportation of ore to foreign countries.

---

[1] Further reference to production and exportation appeared in this journal December, 1913, pp. 673-4.

The "foreign invasion" is regarded as a myth and dismissed as a fancy of ultra-conservationists. A further point raised is this: If the government withdraws radium-bearing land from entry what is to prevent an extension of that policy to mineral land containing gold, silver, lead, zinc and copper.

It is plainly the fear of the state authorities that an act of withdrawal will result in unnecessary delay in the final disposition of the lands, and that a condition will be created similar to that which has existed in Alaskan and Western coal lands. There is also a feeling that more rapid development will take place under conditions of free prospecting by individuals than under government supervision and control. In short, the attitude of the state in this question is but an instance of the general opposition in the West to federal conservation as exemplified in some previous cases.

### What the Government Proposes to Do

The other side of the question has not been as thoroughly ventilated, and much of the state's criticism has been made without a knowledge of the details of the government's true proposal. The withdrawal of the land in question has been considerad for some time, but the proposed method of doing it has only recently been announced. Strong opposition developed, even among federal officials, against the usual procedure of withdrawal under the Land Office regulations; for while tho act of withdrawal would be a simple matter and quickly done, the more important matter of immediate exploitation of the deposits would not be so easily accomplished. The production of radium was recognized as being of prime importance, not only to the states containing the mineral deposits, but also to the entire country.

The plan finally proposed can be given best in the words of the Secretary of the Interior, in a letter to Congressman Foster, chairman of the House committee on mining: "The Secretary of the Interior should be authorized (by Congress) to conduct explorations and researches with a view to determining the practicability of developing from such ores (carnotite) a supply of radium, and also authorized by lease or otherwise to provide for the mining and treatment of radium-bearing ores in such manner as would best secure a supply of radium for the use of the government of the United States and the hospitals of the country."

An analysis of this statement will reveal intentions quite different to those assumed by western mining men. The significant parts of the statement are that the Secretary seeks authority "to conduct explorations and researches," and to "lease or otherwise provide for the mining and treatment of radium-bearing ores." The mere withdrawal of land from entry, without automatically providing for mining and treatment of ore, would be intolerable; and any resolutions on this subject passed by Congress should carry adequate and proper provision for exploration, mining and treatment, either by lease to private parties or through governmental agency, probably the Bureau of Mines.

There are arguments on this side of the question, as on the other. Those who favor the proposed federal plan contend (1) that the states (Colorado and Utah) will benefit by the activity of the government; (2) that no present owners or operators of radium-bearing land will be injured; (3) that the production of radium is such a marked exception in the mineral industry as to be entitled to special consideration from the government; (4) that more active and intelligent prospecting will be done under government supervision; and (5) that an adequate supply of radium for this country can be obtained most quickly and cheaply through governmental agencies.

Practically the only persons who can be injured under this plan are future prospectors, but even they can profit by making special effort to locate claims pending final action by the government. Up to date comparatively little prospecting has been done on personal account. Most of the work has been done by paid agents of the large companies, and even this has been confined to locating claims on which outcrops were plainly visible. Such deposits are now privately owned and the ores can be sold when and where the owners wish. Prospecting and exploration on a systematic basis might develop further deposits; but in view of the physical difficulties attending such work in those parts of Colorado and Utah containing the carnotite deposits, few individuals have undertaken to prospect; but even they could not do the work on a scale anticipated by the government.

Undoubtedly great pressure has been brought to bear on the government, through medical societies and other agencies, not so much to prevent the exportation of radium ore from this country, as to produce as soon as possible an adequate supply for domestic use. A great deal of such ore is going abroad, and one unfortunate feature of this is that American users can buy but little of the radium produced from their own ores, even at the rapidly rising speculative prices. The government stands for the local production of radium, possibly at Denver or some suitable western city, for the purpose of supplying the material at a price fairly commensurate with the cost of production. This would eliminate the speculative feature of present prices which have practically doubled in the last year. The government would be able to control only such new deposits as it might purchase or discover by exploration, and only such ore as it could buy from present claim owners. There would still be a comparatively large quantity available for purchase by foreign concerns.

### A Case for Cooperation

No ultimate good can come of a prolonged fight over this question. It is a time for coöperation of the different interests. All of the facts should be considered on their genuine merits, to the end that this country may take advantage of what appears to be a wonderful opportunity. The West will profit in any event; but the circumstances of the case are such that it should profit in a way that will be a credit to the whole country. If a fight is precipitated in Congress it might result in a mere withdrawal of the land without financial provision for exploiting it, which would be a most unfortunate outcome. If the states should wage an unsuccessful fight on the matter of withdrawal, they would then be in a poor position to influence congressional appropriation for mining and treatment.

The daily press has been filled with a lot of senseless twaddle and half-truths on this subject, some of which is plainly inspired by personal interests or born of political necessity. It serves no useful purpose, but tends to create false impressions. No satisfactory settlement of the proposed conservation can be reached without a knowledge of the whole truth.

The type of conservation which has found acceptance in this country is that which utilizes our resources to meet present needs without undue waste. Perhaps the matter of producing radium is a case in point. The element already has proved a wonderful therapeutic agent. The demand exceeds the supply. We have the raw material and we ought to make the best use of it now. Hence the legitimate opposition to a withdrawal of the land containing it, without automatically providing means for proper exploration and the ultimate production of radium for domestic use.

# Handling the Raw Materials at the Iron Blast Furnace

BY J. E. JOHNSON, JR.

*(Concluded from January issue, page 53)*

### Design of Bins

We can now turn to the bins which serve for storage of the raw materials going immediately into consumption.

These bins are of many types, bins having had a development covering many decades. Substantial and well designed wooden bins were in use at a few plants thirty, forty and fifty years ago. But the great storage required for modern plants necessitated one and frequently three or four tracks on top of the bins, all of which must carry the most heavily loaded railroad equipment. This, with the excessive maintenance of wooden structures, has gradually forced the introduction of steel bins, built as an integral part of the structure which supports them and the railroad tracks at the same time. Recently concrete bins also have been used.

FIG. 16—FURNACE WITH BROWN SKIP HOIST AND PARABOLIC BINS

It is useless to try to illustrate all the types of bins which have been used, and I shall therefore show only three of the best known types, which are brought out by the three concerns whose ore-handling machinery has previously been described.

It is necessary to explain that at the large modern plants where equipment of the highest type is used, mechanical filling is now practically universal, and these bins are not therefore designed to discharge into filling barrows, but into the modern successor of the filling barrows, the scale car.

The design of gates for bins is a matter the difficulty of which in practice is as great as its simplicity appears to be on cursory examination. The material to be handled is irregular in size, irregular in shape, rough, as likely as not to be sticky, and more likely than not to have its coefficient of friction greatly altered by a change from dry to wet. If the gate opens and closes from above, guillotine fashion, it may just happen to catch the largest lump passing, which may be too strong to be crushed, and holding the gate open will leave room for a rapid flow of finer material under it. If the shape of the chute be not right the material will jam and bridges exercising apparently almost human, not to say devilish ingenuity, in building an arch which quickly cuts off the flow of material from the bin, and which cannot be broken outward because the material is under compression, nor inward except with the greatest difficulty because the pressure of all the material in the bin lies against it.

More than one case is on record where an engineer or furnace manager has designed a new type of gate for a bin, taken a guest out to see how beautifully it operates, and then had it fail so completely that the filling barrow, or even the scale car, would be buried up because the material could not be shut off when the "improved" gate was brought into play.

Even if these fundamental difficulties be overcome great care is necessary in placing the spouts on the bins and bringing them sufficiently close together so that material does not build on the space between them and in time almost fill up the bin. This may seem like an extreme statement, but I have seen bins of the very best construction and most carefully designed, which looked to be full of ore, but on a closer examination two holes, three or four feet in diameter, were to be seen running down from the top to the two chutes below. These holes would represent almost the only free-flowing capacity of the bin. The ore being plastic and sticky, had built up upon the base of the bin and the bridge between the spouts, until the capacity of the bin was almost gone. This is likely to happen to some extent with any design, and the only way to meet the situation is to dig the bin out at frequent intervals, as the rapidity with which the ore builds is increased as it gets a larger and larger foothold.

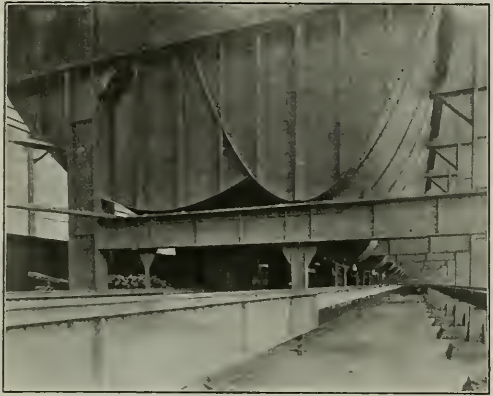

FIG. 17—PARABOLIC BINS

It was with the object of overcoming these various difficulties and furnishing bins whose flow would be under the absolute control of the operator that the three designs now to be described were brought out.

Taking the designs of the three builders mentioned in the same order as before, Fig. 16 shows a "parabolic" bin designed by the late Alexander E. Brown, of which the principle is taken from the fact that when a liquid or semi-liquid is suspended in a trough of flexible material, the cross section assumed by the trough is a parabola, therefore by giving the bin this shape, stresses tending to deform it are eliminated, and only its weight needs to be considered. These bins are suspended from heavy girders, which in turn are supported by steel columns. The complete parabola at the left is for ore. The incomplete one of greater width, on the right, joined to the ore bin at the left, is for coke.

The spouts on these bins with their gates in the form of cylindrical quadrants are plainly shown at the bottom, as is also the scale car beneath them. A locomotive crane standing on an adjacent trestle, and in a position to discharge ore into the railroad car standing on the bin trestle, is also clearly shown.

The construction of the bins is well shown by the photograph (Fig. 17).

Fig. 18 shows the bottom of the bins with their chutes, also the scale car and its operator. It will be seen that the quadrant gates are operated by a pair of connectng rods attached to crank pins, carried on a heavy gear shaft, supported at the top of the chute. The large gear is driven by a pinion which in turn is driven by a pair of beveled gears. From the vertical shaft of the driver of these depends a shaft carried by a universal joint and carrying a socket at its lower end. The scale car carries a square-headed shaft, which can be thrown up by the operator to engage with the socket for any chute. After this is done a small motor is started and the gears revolved until the crank pins come to the bottom position, at which time the gate is wide open. When the required amount of stock has been drawn the gate is raised by revolving the large gear shaft through another half revolution.

The style of bin and chute designed by Hoover & Mason is shown in Fig. 19. No attempt is made in this bin to use the parabolic shape, which is open to the objection that its angle changes, so that while it may be steeper than necessary in some portions it is flatter than necessary in others, and the latter condition prevails near the bottom, where the flow should take place most freely.

The bottom of the bin is formed by a horizontal roller five feet in diameter which lies close to the bottom edge of the chute, so that no material can get between the two. This can be rotated at the will of the operator in the direction shown by the arrow. The angle from the top of the chute opening in the bin to the top of the roller is considerably less than the angle of repose of the material, so that no material can possibly get out of the bin when the roller is stationary. On the other hand, when it is rotated the material is carried forward by the roller to a point at which its slope is greater than the angle of repose of the material, which then slides off. When the roller is stopped the flow of material instantly ceases.

The front of the bin is built with louvre with a reverse slope, through which it is impossible for the material to make its way out, but through which it is very easy for the operator to thrust in a bar and break any bridge or arch that may form to obstruct the flow.

The roller is driven by means of gearing thrown in by a clutch worked by the operator. The gearing is actuated by a line shaft or driving shaft, which runs continuously. There is a separate roller for each discharge, the equivalent of each chute in the older type of construction, and the design is such that the ends of these rollers come very close together, leaving a mimimum of space between them, so that the bin is practically open at the bottom all the way along. This to a great extent prevents the formation of accumulations of ore, as these have no foothold on which to begin to form, the bottom of the bin being kept clean by the continuous sliding of the material over it, and no bridges between chutes existing. For the coke bin the roller is perforated, and by an ingenious arrangement made to serve as a screen for the removal of the fine material from the coke. This action is always complete and automatic because the roller cannot run as a feed device without also acting as a screen.

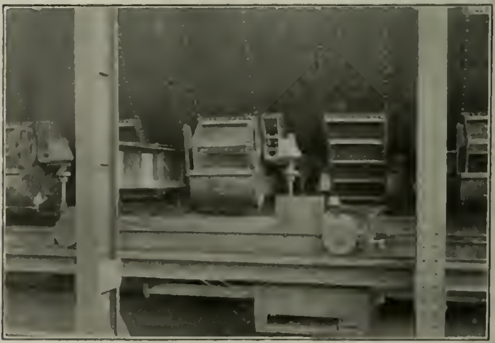

FIG. 18—BOTTOM OF BROWN HOIST BINS WITH THEIR CHUTES, AND SCALE CAR WITH OPERATOR

The transfer car used in bringing the ore from the

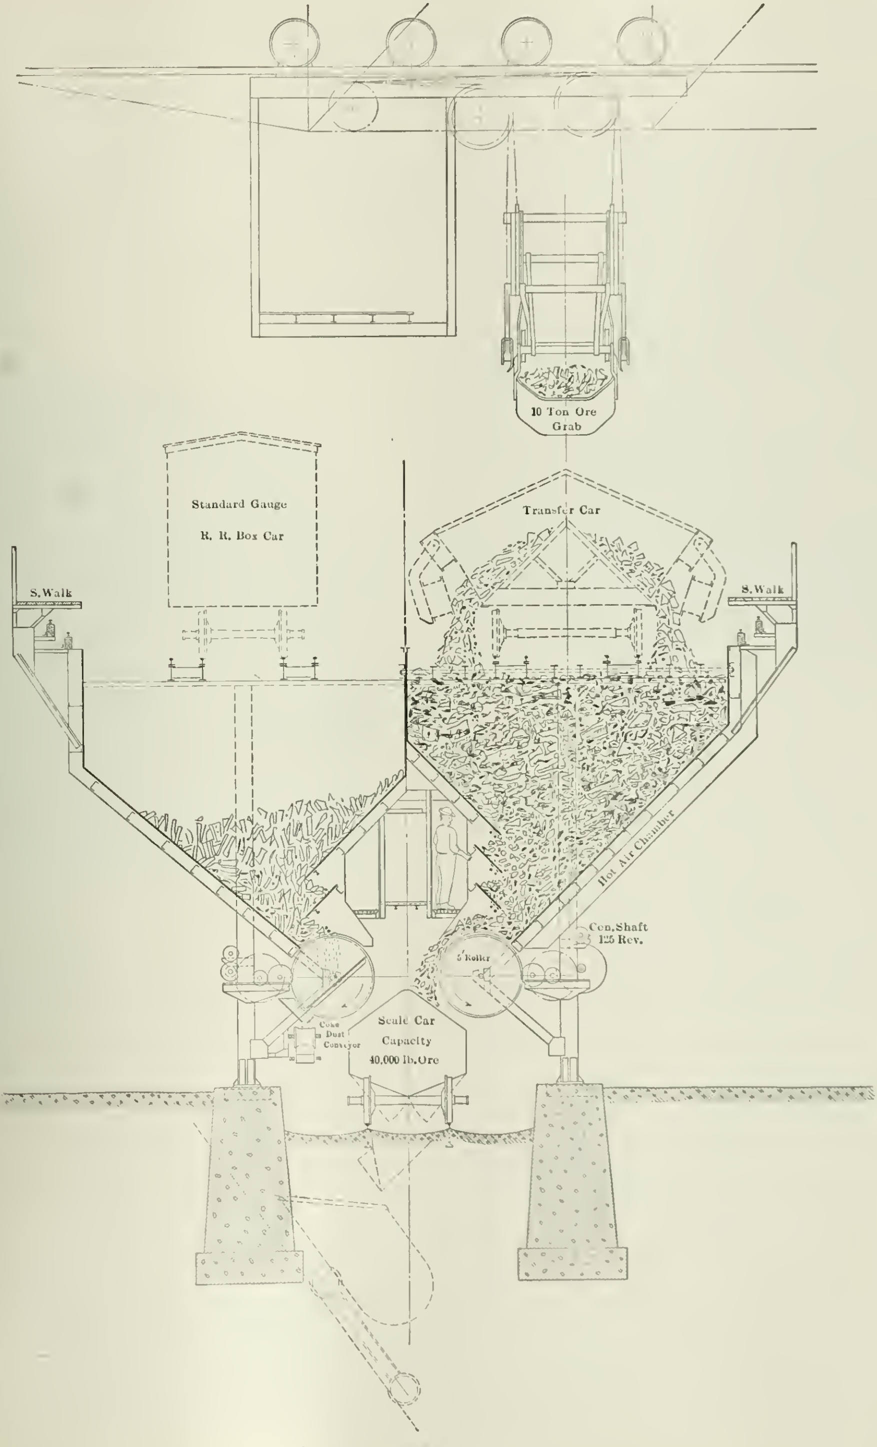

FIG. 19—HOOVER & MASON BIN AND GATE

bridge to the bin is shown in dotted lines above, as is also the overhanging end of the ore bridge with its grab bucket and trolley.

A gate has been introduced by the Wellman-Seaver-Morgan Company, which is on the same principle in all particulars as that of Hoover & Mason except that the former use an endless belt made by overlapping metal slats mounted on sprocket chains, as shown in Fig. 20, instead of a roller. The pressure of the stock on top of this is taken by beams lying inside the endless belt, on which the upper half of the belt slides. Owing to the location of this apparatus up underneath the bottom of the bin, the construction is not as clearly shown by the photograph as might be desired, but the overlapping metal slats and the sprocket chains are visible, and the operation will be understood from the description of the Hoover & Mason apparatus. The metal belt acts as a bottom to the bin and carries the material bodily forward until it drops over the driving-sprocket end into the scale car.

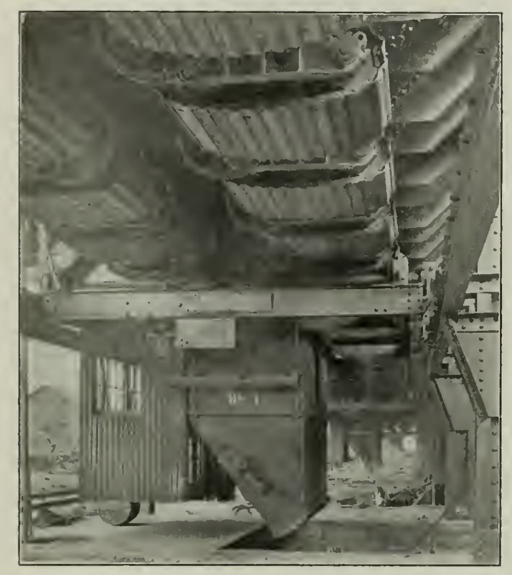

FIG. 20—WELLMAN-SEAVER-MORGAN GATE—ENDLESS BELT MADE OF OVERLAPPING METAL SLATS ON SPROCKET CHAINS

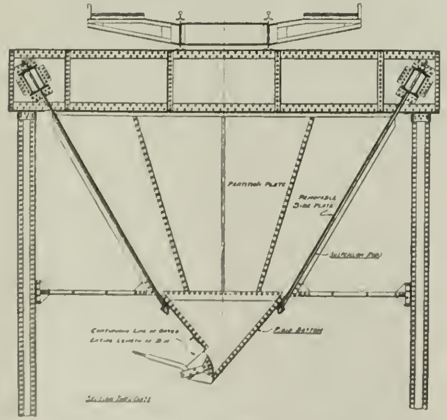

FIG. 21—HEAVY STEEL "BAKER" SUSPENSION BIN WITH HAND-OPERATED QUADRANT GATES

It will be noted that all three of these designs which jointly have probably been applied to a greater tonnage of bin capacity than all other types combined use power for the operation of the gates.

This is because of the difficulty that has often been met in operating hand gates quickly and positively, to which I have already alluded. At the same time it must be understood that many hundreds of bins are in successful use with hand-operated gates, which have the advantage of greater simplicity and lower first cost than any of the power-driven gates.

Fig. 21 shows an outline drawing of the Baker suspension type of bin built by Arthur G. McKee, Contracting Engineer, Cleveland, Ohio. The gate in this type of bin is a quadrant of a cylinder, but in the reverse position to that used on the Brown bin. The axis of the cylinder is so located that the flow of the material tends to close the gate, so that it is not liable to be opened accidentally. The gate is operated by the scale-car operator through the lever shown in the drawing.

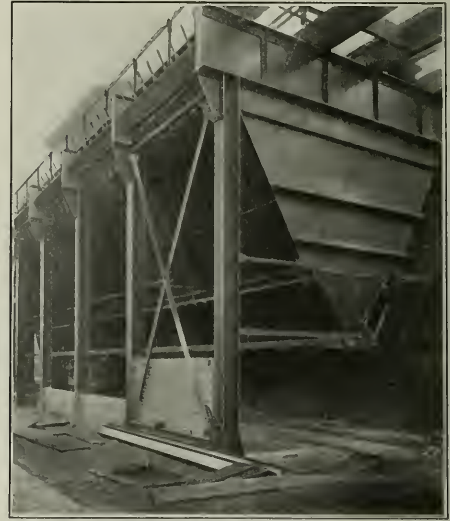

FIG. 22—MC KEE-BAKER SUSPENDED BIN WITH CONTINUOUS LINE OF GATES, HAND OPERATED

Owing to the absence of machinery these gates are only separated from one another by the small space necessary for clearance, so that the opening in the bottom of the bin is continuous and the formation of bridges and building up of the ore inside the bins is thereby to a great extent prevented.

These bins are, like the Brown, of the suspension type, but instead of their cross section being that of the true parabola it is made up of four tangents thereto, which give to a large extent the same freedom from distortion that comes from the use of a true parabola, any minor stresses of this nature being taken up by the transverse partition plates and the rigid bottom.

A considerable tonnage of these bins is in successful operation at various plants and there are many others with other types of hand-operated gates, many of which are entirely successful.

### Methods of Hoisting in Mechanical Charging

In hoisting for mechanical filling, as apart from distribution (the latter being used in the technical sense of distributing the stock properly in the top of the furnace), there are two main systems in use to-day, and a third which is a combination of some of the features of each.

In the first system the stock is drawn from the bins into large round buckets, whose bottoms consist of a cone, or "bell," attached to a rod running up through the center to a hook at the top. This bucket is then transported to the bottom of the hoist and sent up, hanging by the hook at its top, to the top of the furnace, on which it is seated and then dumped by lowering the hook on the central rod carrying the bell, which is merely a large conical valve. In this system the material does not break bulk from the bin to the furnace top.

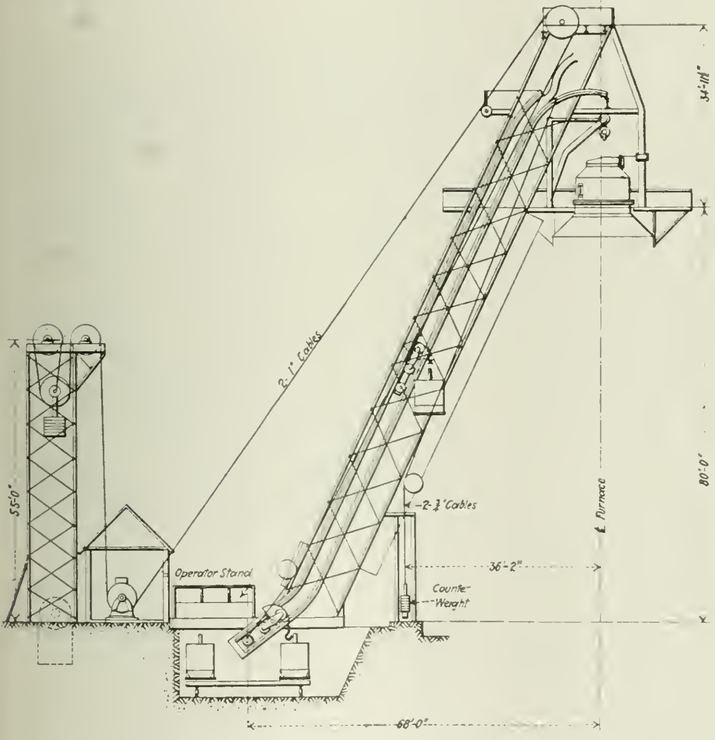

FIG. 23—FORD-PARKS SYSTEM OF BUCKET FILLING

Different systems of rotating the buckets are in use, but this subject can more appropriately be discussed under the head of stock distribution. Various methods have also been used for lowering the bucket onto the furnace top after it reached the proper position. But while these differ from the one illustrated, they do not differ sufficiently in principle to make detailed description necessary.

In the other system a sort of tank, either rectangular, round or elliptical, with wheels on one side, runs from a pit beneath the filling level to a hopper above the furnace top, where it turns upside down and dumps, then returns to the bottom, its travel being thus confined entirely to the inclined track running to the furnace top, known as the skipway, the tank itself being known as the skip.

This skip is usually filled from a motor-driven dumping car, with its body or dumping hopper mounted on a scale carried by the truck, called the scale car or larry. This car is traversed along in front of the bins and filled from them. It is then returned to a hopper or chute, which delivers into the skip when the latter is in its bottom position, and there dumped, returning for another load while the skip is hoisted to the furnace top.

In this system it will be seen the stock breaks bulk between the bins and the top of the furnace.

At some plants a combination of these systems is in use, in which the bucket with the bell bottom is never removed from the suspension truck on which it is carried, or only to a turntable serving it, and plies therefore only on the incline, being filled by a scale car exactly the same as a skip. The bucket in this case virtually becomes a skip which dumps through the bottom while retaining its upright position, instead of being turned upside down, as is done with the regular skip.

The first type of distribution is shown in Fig. 23, which shows the Ford-Parks modification of the original Nieland top.

The second of these styles of hoisting is well shown by Fig. 16, which is the design of Alexander E. Brown, and with which in connection with the distribution at the top of the furnace we shall deal more at length later.

Many variations of each of these systems are in use. Very frequently in the case of the skip hoist the coke bins are arranged on each side of the skipway, and coke is spouted directly into skips without the intervention of the scale car, the bulk of the coke being taken by skipfuls instead of its weight. This is a very satisfactory system if the same coke is always used, but one liable to produce great derangement of the furnace if sudden changes are made from one coke to another of very different density.

The skip hoist is built with both single and double skips. The advantage of the double skip is that it is perfectly counterweighted, without extra mechanism for that purpose, and that it has a very great capacity. It, however, labors under the disadvantage that it discharges the stock at two points, one each side of the central plane, rather than at one point exactly in the central plane, as is done with the single skip.

Where the irregularities of the distribution are not compensated or eliminated by suitable means, the lack of symmetry, due to the fact that the skips dump on opposite sides of the main central plane and on the same side of the central plane at right angles to it, is likely to cause very serious derangement of the working of the furnace. The elimination of these irregularities is made much easier if the skip dumps exactly in the central plane.

A double skip was put in use at the Pueblo plant of the Colorado Fuel and Iron Company a number of years ago, designed by Mr. E. G. Rust, in which the advantages of both the single and double skips were obtained by a most ingenious design. Both skips run in the central plane and occupy the same positions at top and bottom. Of course when one is at the top the other is at the bottom, and there is no fouling in those positions, but in order that they may pass each other the tracks diverge from one another in the vertical flumes starting from the top and bottom so that they are separated vertically at the middle of the skip bridge by a sufficient distance to allow the under skip to pass beneath the upper. The gauge of the track for the upper skip is wider than that for the lower, which runs between the rails of upper track. The deepening of the skip bridge at this point tends to give it additional strength at the place it is most needed.

This system has been in use at the Pueblo plant for a number of years, but for some unknown reason its use has never extended very widely.

### Location of the Hoisting Sheaves

One of the difficulties met in skip hoist design is that commonly the hoisting rope must run over a sheave located at the upper end of the skipway and come back over the top of the skip in order to be out of the way of the stock when the skip dumps. This brings the rope above the skipway while the hoisting engine is generally most conveniently located underneath the skipway.

Various arrangements have been used to overcome this difficulty. In one design a truck is used which carries the skip at its upper end and practically pushes it up the incline, the skip being pivoted to the truck and having an auxiliary pair of wheels in the front. In this case the sheave is put below the skipway and is far enough below the skip when it dumps to be out of the way. This puts the rope under the skipway where it is most desirable to have it.

In a number of cases the ropes have been carried clear over the top of the furnace, and the hoisting engine placed on the opposite side in order to overcome this difficulty, while in one well known type of top two guide sheaves are used on each skip rope, in addition to the main hoisting sheave, in order to get the rope out of the way at the top and pass it back underneath the skipway.

In the Brown design of skip hoist the difficulty is solved by the use of the single skip, and by putting the hoisting sheave in a plane parallel with the skipway as shown in Fig. 16 so that the hoisting rope can be returned over one side of the skipway to the engine house beneath it.

Probably other solutions of this apparently trivial problem have been attempted or made, but these are the ones best known and most used.

### Dumping the Skip

The method for turning the skip over to dump is universally the same. The main rails of the skipway bend down from the incline and run in level when they reach the top of the hopper, but there are two additional rails set to a somewhat wider gauge which continue on in the main line of the skipway. These are set far enough apart so that the front wheels can pass through them without touching the wheels, all being outside the skip. But the rear wheels have a supplementary tread outside the regular one, which comes onto these supplementary rails just where the main rails bend down from their straight line. This carries the rear wheels on up while the front ones go forward on a level line, and in something less than twice the length of the skip it is turned up to an angle of forty-five degrees or more and so emptied completely.

### Counterweighting

The bucket type of filling must use a counterweight in order to avoid excessive consumption of power, and somewhat more difficult control in handling its loads, because from the nature of the case the bucket type of filling must be of the single-hoist variety and therefore unbalanced.

Various methods of arranging the counter-weight are in use. Very generally a vertical tower is used of somewhat less height than the furnace, in which a weight is raised by the counter-weight rope, when the skip is going down. A system of sheaves is used like an ordinary block and tackle in order to get the required counterweighting effect with a short travel by using a proportionately heavier counterweight.

The Brown skip hoist when designed for a single skip eliminates the problems of reversing the engine and of counterweighting the skip by using a hoisting engine in which the drum is connected to the engine shaft through a friction clutch under the control of the operator instead of the ordinary hoisting engine in which the drum is keyed to its shaft and positively connected to the engine shaft through gears. The engine runs always in one direction and the skip is hoisted by throwing in the clutch. On the return trip the skip is allowed to run back by throwing out the clutch and controlling the drum with a brake.

The better type of engine which can be applied by eliminating the need for reversing makes this system more economical, in spite of its loss of power in hoisting the unbalanced skip, than the ordinary system is with the skips balanced, but using the very uneconomical type of reversing engine previously described. The Brown system, however, is open to the objection that it requires some skill on the part of the operator in throwing in and out the clutch and lowering the skip with the drum brake, whereas the counterweighted system can be made entirely automatic as to control, etc., by the use of the slow starting and slow stopping devices previously described.

### Larry Cars

These are almost always used with skip filling and sometimes also with bucket filling. Their essentials are in general always the same, but the details of their arrangement varied greatly. These essentials are a truck, motive power for the truck; a buffer with quick and complete means for discharge and scales supporting the buffer on the truck.

Frequently also there are means for operating the gates. Several of the preceding illustrations of bins have shown scale cars also and from these a good idea of the standing types may be obtained. They may be either of the suspended type with their rails elevated close up under the bottom of the brim which has the advantage that nothing can fall from the chute or buffer onto the rails; or the rails may rest on ties on the ground as in standard railway track.

Many systems of discharge scales have been used and in general the details of the design of these cars is adapted to the conditions of the individual case and the judgment of its designer.

A modified type of larry is used with the original bucket type of filling in which the buckets are removed from the hook of the hoisting truck and taken directly to the bins to be filled, but in this case the more appropriate name of scale car is used.

These differ from the larry principally in having a platform in which the bucket rests instead of a buffer; while, like the larry, their detailed design is adapted to the condition of the given case.

### Scales

One of the most important details of the whole operation of charging a furnace, which as a whole is probably the most important single part of blast furnace operation, is the weighing of the materials. It is customary to look upon the blast furnace as a rough, not to say crude apparatus. This view is justified in part by the enormous forces which it must handle and keep under control. But as a matter of fact in spite of its size it is one of the most sensitive pieces of apparatus in industrial use and runs on smaller margin of safety in fuel than any other of our great industrial operations. Changes of the "burden" (a technical name for the weight of ore for a given fuel charge) as small as one per cent are not infrequently used in adjusting the operation of the furnace to make the kind of iron desired with a minimum consumption of fuel. Changes of two or three per cent are as large as are often made to adjust for the ordinary variations of operation. Such adjustments necessitate accurate weighing, and the lack of this has often been accountable for bad furnace operation, and even more numerous cases in which claims of remarkable furnace work were based upon inadequate or incorrect knowledge of the weights of the different materials actually used. Not infrequently the consequence has been a bitter disappointment when the book inventory of the material on hand was compared with the actual stock of such material.

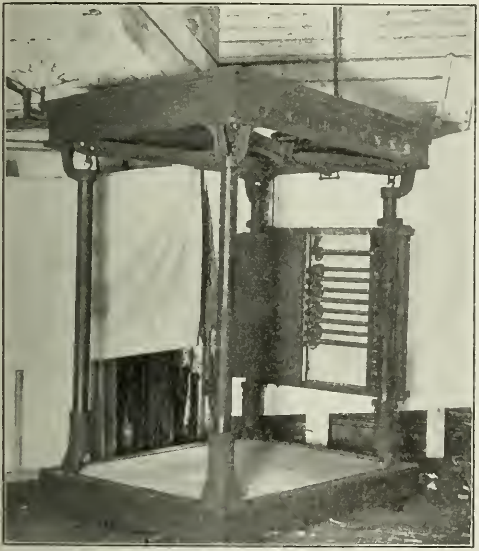

FIG. 24—FURNACE CHARGING SCALE

Cases are on record too numerous to mention in which the books have shown the presence in the stock house of thousands of tons of material, and the financial returns have been estimated on this basis only to find on investigation that the material, so plainly shown by the books, had been put through the furnace and was conspicuous by its absence from the stock house. This has sometimes happened with the knowledge, or even through the deliberate action of a dishonest superintendent, but has also often happened to an honest one who had too great confidence in his scale weights. This condition is now so well understood that the financial management generally insists on a monthly or weekly inventory of the actual material on hand, and its comparison and reconcilation with the figures taken from the furnace books.

The scales used for charging purposes have to meet certain special conditions, and therefore were early designed by the scale makers for this purpose, and given the name of "charging scales."

The type of these in common use with the barrow system of filling is shown in Fig. 24 (Fairbanks & Co.). These are platform scales with the base sunk in the floor of the stock house so as to bring the platform level with the floor. In recent years these have nearly always been of the suspended type, the platform being carried by four suspension rods from the scale-levers over head. This takes the latter up out of the way and out of the dirt in which they were necessarily more or less buried with the older type of scales, in which the levers were in a pit below the platform.

A special condition that these scales have to meet is that as a general thing at least three kinds of material have to be weighed—fuel, ore, and flux (limestone or dolomite), and a definite amount of each is required for each charge.

In order to meet these conditions the scales are built with from three to six separate beams, any one of which can be lifted up out of operation or lowered onto a frame depending from the main beam, so that the two operate as one. The main beam is usually used to balance the weight of the empty barrows, and one of the secondary beams is then thrown in for each material to be filled, its pea being locked fast for the charge weight wanted, this particular beam then rises and falls according to the weight of the given charge in the barrow. When this has been adjusted by adding or subtracting material this beam is thrown out and that for the next material thrown in.

The introduction of mechanical filling brought about the necessity for a different arrangement of the scales, and the trucks which carry the buckets to the bins in the bucket system of filling are provided with scales under the platform on which the bucket rests; or in the case of the larry car used with the skip, the hopper is carried directly by the scales which constitute a part of the truck. The same system of beams has in some cases been used as in the stationary charging scales, but in more recent years it has been found extremely desirable to use a recording type of scale.

The first of these ever installed, so far as known to me, was built by the Streeter-Amet Company of Chicago, for the order of Mr. W. L. Kluttz, now vice-president and general manager of the Central Coal and Iron Company, then superintendent of the Thomas plant of the Republic Iron and Steel Company.

This scale carries a large round dial, around which a pointer travels as the weight on the scale increases. Certain fixed markers are attached to the face of the scale, in positions corresponding to the burden of the different materials wanted, and the scale car operator can then watch the gradual rising of this pointer toward the desired weight, so securing much more accurate weights than is possible when the only indication given by the scale occurs during the brief instant while it is in balance, since then it is generally overloaded before the supply of material running in can be cut off.

These scales are also provided with a paper tape, and by means of a lever, which is pulled when the correct point is reached for each portion of the charge, the actual weight on the scales is stamped on this tape, which is locked up in the scale box, entirely inaccessible to the operator. At any interval desired, generally once a day, this tape may be taken out and examined to see the accuracy of the weights actually obtained, as compared with those called for by the pointers.

The moral effect of this on the scale car operator is tremendous, and vastly better results can be secured by the use of such an apparatus.

The writer became general superintendent of the plant mentioned between the time that this experimental apparatus was ordered and the time it was put in operation. The change produced in the accuracy of the weights obtained was almost beyond belief and the work of the furnace on which the scale was used immediately improved very much.

Since that time the American Kron Scale Company has brought out a similar device by which the same results may be obtained. The practical importance of this matter is so great, and the moral effect upon the scale car operator caused by the knowledge that a continuous record is being made of the way in which he is doing his work, are so important that it is doubtful if any furnace is justified in doing without such equipment.

The scales on scale cars are subjected to a very serious service. They not only have to receive the impact and shock of the incoming material, but they have to stand the much more serious shocks arising from irregularities in the track on which the scale car runs. The great inertia of the charge on a loaded scale car causes enormous stresses on the knife edges even with apparently insignificant irregularities in the track. For this reason switches, cross-overs, and other breaks and irregularities in scale car tracks should be avoided to the greatest possible extent. Moreover, these cars should always be provided with springs over the axle boxes, or in other suitable location. These springs should be the softest, that is, have the maximum travel for a given change in stress, permitted by the conditions, as in this way the springs absorb the shocks arising from the irregularities of the track and keep them off the knife edges.

I have seen scale cars built entirely without springs, and at the same time heard the furnace managers complain bitterly that it was impossible to get his scales to stand up and give accurate service, without his realizing the reason.

Means have been provided whereby the weight of the charge hopper was lifted off the knife edges except during the time that it was actually being weighed. But it is ordinarily difficult to get scale car operators to use this device. There seems no reason why it should not be made to interlock with the traversing motor of the car, so that the latter could not be moved except after relieving the knife edges of the scales from weight.

This may seem a matter of too little moment to deserve such serious mention, but when the importance of accurate weighing previously mentioned is considered, and when it is realized how utterly unreliable the best scales become when their knife edges are even slightly worn, it is believed that the stress laid on this subject will be justified.

## Electrochemical Progress in Norway in 1913

Mr. I. J. Moltkehansen, Managing Director of the Fredriksstad Elektrokemiske Fabriker A. S., communicates to us the following notes which will we assume be interesting to our readers.

The Fredriksstad Elektrokemiske Fabriker A. S. expects to be operating by the middle of 1914 and will manufacture metallic sodium, sodium peroxide, and other sodium compounds such as sodium cyanide, also possibly potassium chlorate.

The sodium works at Vadheim in Sogne has largely increased its output during 1913, having now a producing capacity of possibly four hundred to five hundred tons of sodium per year.

The electric zinc furnaces at Sarpsborg (similar to those at Trollhättan, Sweden) are said to be running profitably. Other proposed electric zinc smelting processes do not seem to have yet reached that stage. Mr. Tharaldsen of Trondhjem is reported to have developed a new electric zinc smelting process at the Ilen Smelteverk. Mr. Raeder of Kristiania is also developing an electric zinc furnace, being backed by a German firm in Nerpelt, Belgium.

The Skienfjord Kraft A. S. has rented 10 to 15,000 horse-power to a German firm, for the manufacturing of silicon and calcium carbide. Prime Minister Gunnar Knudsen is the president of this power company, which is developing several water falls near Skien. Every week there are reports of new companies utilizing large and small water falls in all parts of the country for the purposes of light and power.

In this connection it is interesting to note that, at the same time, modern gas works are being erected in the smaller towns of Norway, mostly for heating and industrial purposes with utilization of the by-products.

The great water-falls of Bjlvefos in Hardanger, and Matre and Tyin in the Sogn district are now being developed. The Government is taking up the regulation of the river Nummedalslaagen by constructing dams and forming lakes in the highlands.

The "Societe Norwegienne de Nitrure" has acquired the Serpek patents for producing aluminium nitride in Norway, with a capital of ten million francs. A plant is being erected at Arendal.

The "Norsk A. S. for Elektrokemisk Industri" has increased its capital from 4 to 6 million kroners. It is not known exactly to what purpose this new capital will be put. This company has started many important electrochemical enterprises in Norway.

The Hardanger Electric Iron and Steel works, at Tyssaa near Odda stopped operations last year. This was one of the enterprises of the Norsk A. S. for Elektrokemisk Industri. This company has formed a mining company "Grong gruber" to work the large pyrites deposits north of Trondhjem. The Dunderland Iron Mining Company is reported as rehabilitated with English capital, to work the low-grade pure magnetite deposits, formerly worked by the Edison methods. They will be worked by a new electromagnetic concentrating and briquetting method, which is expected to give much more valuable and better results.

The old state silver mines at Kongsburg, which have been worked for nearly three hundred years, have in recent years increased their production, until it is now over twenty-two thousand pounds of silver per year. Other rich silver mines have been recently found in the same neighborhood and may soon be operated.

Plans are on foot to start large cement works near Drammen, using the rich limestone from the marble quarries at Lier; the capital is stated as two million kroners.

The "Alby United Carbide Factories" has obtained important concessions from the Government for the development of the Aura Falls near Molde. Mr. Blackstad is directing the company's activities in Norway.

Altogether, 1913 has been a very prosperous year for Norway, especially for the important steamer and sailing ships of the mercantile marine; crops have also been abundant, and there is plenty of money among the people. The importance of new railway connections to open up the country in all directions is being more and more realized. A new railway is projected to connect Kristiania and Trondhjem, having a branch to Molde and Aalesund. Another railway is projected north of Trondhjem to run to Narvik, with a possibility of running farther north. West of Kristiania a railway is being constructed from Kongsberg to Notodden and Telemarken, which will ultimately continue to Christianssand and Stavanger. A railway is also planned between Odda and Haugesund, near Stavanger. The railway between Kristiania and Drammen will probably be electrified in the near future; the railway being built between Myrdal and Fretheim in the Sogn will also be electric.

The Marconi wireless telegraph stations erected at several places on the coast have been of important aid to shipping during the year. In December, two 7000-ton Swedish steamers, the "Norrbotten" and "Italia," were saved by the Marconi station on the Lofoten Islands giving them instructions by wireless and telegraphing for pilots to conduct them to safety. A new station will be opened next summer near Stavanger, at the cost of 2 million kroners, which is expected to communicate directly with Newfoundland and New York.

Another great national enterprise, a connecting link between the Norwegians in America and the remaining half in Norway, is the "Norske Amerika Linje" which commenced in 1913 with two modern twin-screw steamers, the "Kristianiafjord" and the "Bergensfjord," running directly between Kristiania-Bergen and New York. The greater part of the capital of this company is held by Norwegian citizens in the U. S. A. As Norway will celebrate in 1914 the centennial of its present constitution, a great influx of visitors is expected from the United States, and the National exhibition at Kristiania will be opened May 17th of this year. It is expected that all the visitors from America will come by the new Norwegian steamships.

We have spoken at some length of the ocean steamship lines, since they play an important part in the industrial development of Norway, by opening new foreign markets for its products, and supplying new sources of raw materials. Other direct steamship lines from Kristiania to the Gulf of Mexico, Fredriksstad to South Africa, Australia and India have also had a prosperous year, and provide very cheap rates for Norwegian exports.

One Norwegian industry has not participated in the general prosperity, viz., the wood-pulp and paper industry. This industry is suffering from too great capacity of production, and raw material has advanced greatly in price. Large steamers arrive at Fredriksstad and Sarpsborg from Finland and Russia loaded with wood for the wood-pulp factories on the River Glommen. An English-Norwegian enterprise was the sending of a steamer of 1600 tons around the north of Norway and of Russia far into the River Jenissej in Siberia, under the guidance of Prof. F. Nansen, returning with a cargo of the much-needed wood. This water way promises much for the Siberian lumber trade and exports, as well as for Siberian importations from Europe because of cheap freights. Prof. Nansen was very cordially received by the Russian and Siberian authorities and a company has been formed to exploit this new trading route.

The Teckniske Hiskole of Trondhjem will turn out its first class of graduates in the summer of 1914. This Institute can at present accommodate 100 students in each year of a 4 years' course. It is projected to double the capacity, so that Norwegian engineers can get their higher technical education at home, instead of going abroad, as they do, mostly to Germany.

The idea of holding in 1916 a joint meeting in Norway, of the Bunsen Gesellschaft of Germany, the Faraday Society of England, the Société de Chimie Physique of France, and the American Electrochemical Society will meet with great enthusiasm in Norway, where the electrochemical industries have recently combined in a union for the protection of their common interests. The Editor of "Teknisk ukeblad," the foremost Norwegian technical paper in Norway, is forwarding the project enthusiastically.

# High-Temperature Resistivity of Refractories; a New Method of Measuring, with Results for Alundum

BY EDWIN F. NORTHRUP

In connection with the commercial application of electrothermics, even more than for its scientific interest, it is important to have a method for rapidly and precisely measuring the electrical resistivity of refractory materials at the high temperatures at which they are used. With such a method available not only trained investigators but students seeking subjects for these might employ their time to good advantage in obtaining a series of values for all the common refractories which are in use in electric-furnace practice.

While the writer has other problems which are absorbing his attention and is unable to find time to make a series of determinations of the resistivity of refractories, he was compelled to devise and test out a method, as supplementary to his other work, for measuring to a temperature of at least 1600 deg. C. the electrical resistivity of alundum cement. The test of the method proved that it is so easily applied and gives such concordant results that it seems wise to describe it here in the expectation that it will meet with favor and be put into practise by others and that we shall not have to wait long to have tables of constants and sets of curves of the electrical resistivities of the commercially useful materials which stand high temperatures.

That these measurements have not been made before is probably due to the fact that without special devices the difficulties in the way of making the measurements are insuperable. As the value of the data rapidly increases with attainment of higher temperatures it is necessary to be provided with a furnace which will meet the following conditions:

A temperature of over 1600 deg. C. must be obtainable.

The temperature must be uniform over a considerable length of the furnace chamber in order that all parts of the refractory being measured will be submitted to the same temperature at the same time, and this temperature must be under perfect control. The furnace chamber must be filled with an atmosphere of carbon monoxide, because, as will be subsequently shown, graphite makes the most suitable electrodes between which to clamp the refractory material being measured and graphite will burn up in an oxidizing atmosphere.

Alternating current must be used for the measurement. If a refractory material be clamped between two electrodes and then be submitted to a high temperature it will be found that when a feeble direct current is passed through it, it develops back electromotive forces as if it were a kind of storage battery. Electric conduction at high temperatures, in these cases, is probably a mixture of electronic and electrolytic conduction. The problem in making the measurement is, therefore, not different than the problem of measuring the internal resistance of a battery.

If the material being measured is clamped between two flat surfaces of conducting material, as graphite, a little consideration will show that there is no material available which can be used to press the two surfaces upon the refractory so as to give good contact without forming a shunt upon the resistance being measured. This difficulty, which for a time appeared to the writer unsurmountable, has been absolutely overcome as will later appear.

The measuring current must be conveyed to and from the material under measurement with something which conducts well when the temperature is over 1600 deg. C.

Up to 1600 deg. C. the temperature may be measured with a platinum vs. platinum + 10 per cent rhodium thermocouple. A casing for the couple of Royal Berlin porcelain will stand this temperature provided the porcelain tube is not in contact with anything. As it is quite viscous at 1600 deg. C., it will be deformed by anything it touches and the glaze will cause it to adhere tenaciously.

In the measurement described this means was adopted for measuring the temperature and the temperature was not carried higher because of the limitation of the couple. The writer has under development a far superior method for measuring a temperature with very great precision which will be described in a later report. It is not an optical or radiation method.

All the requirements for accurately measuring the resistivity of refractories are met by the method which is now to be described.

The refractory material to be measured is first molded in three thin rectangular slabs. The size of these slabs, which was adopted in the measurement here described, was width 3.4 cm, length 4.8 cm and thickness 0.25 cm. As the details for treating the refractory material to be measured would differ somewhat according to the nature of the material being measured, the description here given will apply specifically to the material which was measured in testing out the method. This material was a very finely ground alundum cement made by the Norton Company, Worcester, Mass., and designated by them as grade RA 355. To mold these slabs it is necessary to add to the cement a very small quantity of water and then press the material into a metal mold under considerable pressure. When dried out in a gas oven the slabs are sufficiently coherent to handle without breaking.

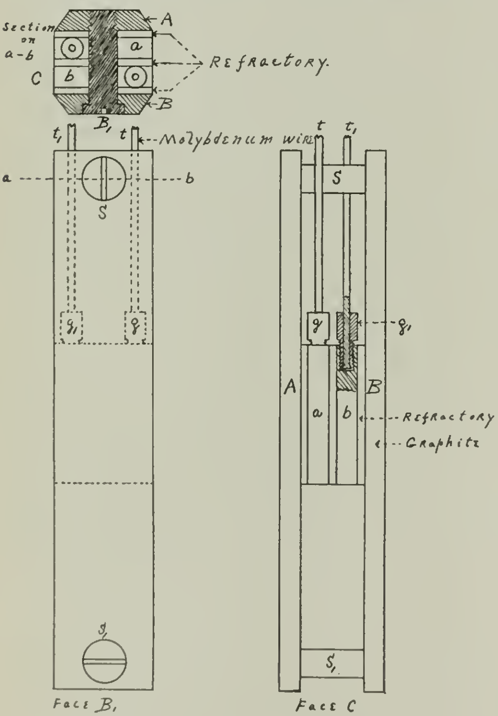

FIG. 1—ARRANGEMENT OF TEST

These three slabs are now clamped between graphite plates in the exact manner shown in the drawing, Fig. 1. In the drawing, *a* and *b* are two graphite plates of the same width and length as the slabs of refractory but about 0.8 cm thick. *A* and *B* are two other slabs of graphite of the same width as *a* and *b* but considerably longer. As actually used in the experiment the A and B slabs were made 9 cm long, but the writer's experience shows that they should have been made at least 25 cm long for a very important reason; the graphite screws S and $S_1$ serve to clamp tightly together the three refractory and the four graphite slabs, as Fig. 1 plainly shows. As there is more or less expansion or contraction of the refractory material when submitted to great temperature changes, it is necessary in order that uniform pressure be at all times maintained on the refractory pieces, that the slabs A and B be long enough so that the natural spring of the graphite may act to maintain the pressure on the refractory pieces.

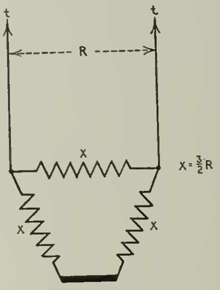

FIG. 2—ELECTRICAL CONNECTIONS

Electrical connection is made in the manner indicated in Fig. 1 to the graphite slabs, *a* and *b*. The two wires which serve as terminals are made of molybdenum approximately 2 mm in diameter. This wire melts above any temperature obtainable in the furnace and as there is a CO atmosphere in the chamber the wire does not oxidize. The wires are fastened to the slabs *a* and *b* with graphite screws $g$ $g_1$ in the manner shown in Fig. 1. It will be noted that we now have an electrical circuit between terminals $t$ and $t_1$ which is like that diagrammatically shown in Fig. 2.

If we call R the measured resistance between terminals $t$ and $t_1$ and $x$ the unknown resistance of each one of the similar slabs of refractory, we have

$$R=\frac{x.2x}{3x} \quad \text{or}$$

$$x=\frac{3}{2}R \quad \text{.............................} (1)$$

If $l$ is the thickness of one slab and S is its cross-section, namely its width by its length, and $\rho$ its specific resistance in ohms per cm³, we have

$$x=\frac{l}{s}\rho \quad \text{.............................} (2)$$

From Eqs. (1) and (2)

$$\rho=\frac{3s}{2l}R \quad \text{.............................} (3)$$

With the dimensions chosen for each of the slabs of refractory 3s/2l equaled, within the limits of accuracy of the measurement, just 100. Hence

$$\rho_t=100\ R_t \quad \text{.............................} (4)$$

The subscript $_t$ means that $\rho$ and R are determined at the measured temperature t° C.

The arrangement shown in Fig. 1 was placed in the bottom of the tubular chamber of the furnace. (This furnace was described by the writer in Metallurgical and Chemical Engineering, January, 1914.) The two molybdenum terminal wires passed up through a cylindrical cover piece of baked lavite which tightly closed the top of the furnace. The thermocouple tube passed through this cover piece and the end of the thermocouple was brought close to the refractory pieces being measured. The two projecting molybdenum terminals were joined to the X posts of the bridge arrangement to be described, and the thermocouple e. m. f.'s were read with a potentiometer. The cold junction of the thermocouple was maintained at 0° C. by being located in ice water in a Dewar flask.

Experiences with this and previous measurements had taught the writer that the chemical composition of all refractory materials is not in an equilibrium position when raised to a high temperature which is higher than that at which it has previously been raised. It therefore, becomes necessary before starting to make measurements to pre-heat the material to a temperature as high or higher than that which one intends to reach in the measurement. Before beginning the measurement, for obtaining final values, the material was heated twice to over 1500° C.

As was expected, it was found impossible to make measurements having any accuracy using direct current. As soon as attachments were made to the X post of a bridge a galvanometer of 1 megohm sensibility would fly off the scale. The writer does not like to make measurements with alternating current using a telephone as a detector, because a telephone does not tell whether the balancing resistance is too high or too low. He prefers an electrodynamometer method. This method has been described by the writer in his book on "Methods of Measuring Electrical Resistance," paragraphs 1113 and 1120. The method enables one to measure the internal resistance of a battery or any device which includes an electromotive force in its circuit with quite as much ease and certainty as one would measure a metallic resistance. The electro-dynamometer suitable for the purpose is the one described by the writer in paragraph 1001 in the above-mentioned book. This was the instrument used in obtaining the resistivity of alundum cement and the method as applied will be readily understood from the diagram, Fig. 3. 110-volt alternating current was used. The condenser C in the diagram was 1 micro-farad and the current which passed through this condenser was quite sufficient for adequate sensibility.

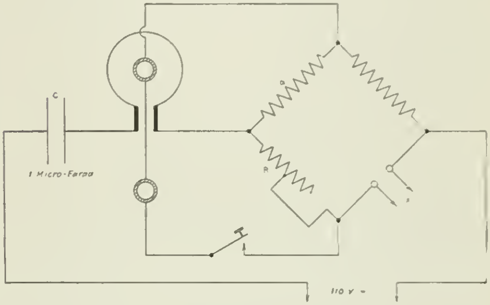

FIG. 3—METHOD OF MEASURING ELECTRICAL RESISTANCE

The measurements of temperature and resistance were taken with rising temperature in the furnace. This is preferable to taking measurements with falling temperature because with rising temperature everything is expanding and the refractory pieces are maintained more tightly clamped between the graphite slabs.

The curve, Fig. 4, shows the results obtained.

———It was suspected that the inflection in the curve which occurs at a temperature of 1100° C. was an error. Therefore, the clamping pieces were removed, refractories examined and everything re-assembled and the measurement was repeated. The inflection occurred the second time at almost precisely the same point and it is concluded that it is a real phenomenon connected with the material. Whether it exists or not, however, has small bearing upon the engineering aspects of the properties of alundum.

The greatest chance for error in these measurements arises from the difference in the resistance which may arise from varying pressure of the graphite slabs upon

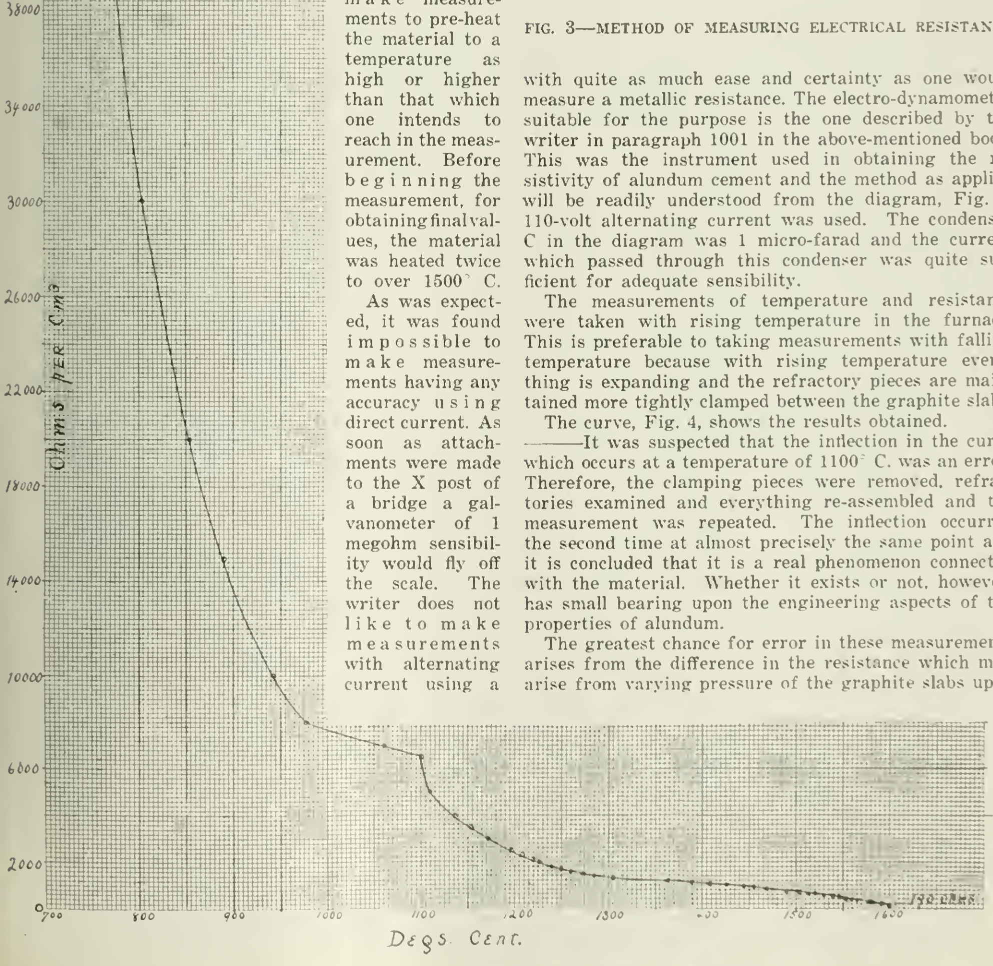

FIG. 4—RESISTIVITY OF ALUNDUM AS FUNCTION OF TEMPERATURE

the refractory pieces. To assign a probable precision to the points on the curve would require more repetitions of the measurement than the writer's time will permit him to undertake. Relative values can be very closely relied upon, say within 2 or 3 per cent, and absolute values, the writer thinks, can be trusted within 10 or 15 per cent. After all, it is only the order of magnitude and the manner of variations of the resistivity of refractories which is required, because the composition of all such materials is far too variable to call for the determination of constants to any high order of precision.

Princeton, N. J.

## Dry Chloridization of Ores

BY JOHN L. MALM

It has been my intention to offer for publication no statement on the treatment of complex ores by dry chloridization until it would be possible for me to report the results of successful commercial operation of the process or state the cause of its failure. The excuse for offering it at this time is to supplement a discussion of the subject appearing in this journal, and to supply such general details as have been a matter of special inquiry.

Details of apparatus design or manipulation generally govern success or failure of a process, and therefore are of the greatest importance in the description of any operation. It is, however, impossible to offer complete details of any scheme which has not been in operation on a commercially profitable scale; and even were such the case, details would differ in the treatment of various ores. Such details as are offered here have been determined by large-scale tests under conditions which probably would govern successful commercial operation.

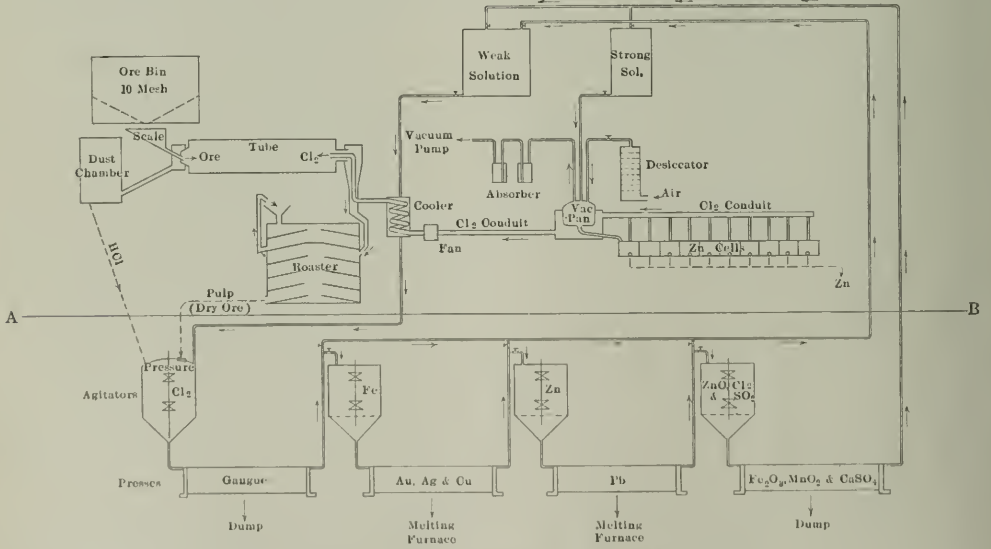

FIG. 1—DIAGRAM SHOWING APPLICATION OF DRY CHLORINATION

With reference to the accompanying diagram of operations, Fig. 1, it is to be noted that the operations indicated above the line *A-B* are to be regarded as standard under my proposed method, while those below the line are suggested only as a probable procedure in handling solutions of the metals indicated.

In the following outline I have found it convenient to reiterate some statements already made in a paper by Mr. A. G. Brownlee, read before the American Mining Congress at Chicago, October, 1911, and in Mr. Harry J. Wolf's description in the May, 1910, issue of the *Western Chemist & Metallurgist.*

### Chloridizing in Tube Mill and Roasting Furnace

The method of dry chloridization is applicable to the treatment of a great variety of sulphide ores, and is independent of the physical condition of the sulphides in the ore. It starts with the ore as it comes from the mine and gives metals as final products, thus combining the functions of a concentration mill, smelter and refinery. Concentrated or separated minerals offer no advantage except in a reduction of transportation charges.

The ore is crushed to about 10-mesh, properly dried and fed to a revolving tube mill, where it is subjected to the action of chlorine gas. The ore is fed continuously at one end of the tube and discharged at the other. The chlorine gas is introduced at the end of the tube from which the ore is discharged. The ore is kept in contact with the gas long enough to chloridize from 40 per cent to 70 per cent of the metal contents. In the treatment of ore containing more than 10 per cent sulphur combined with iron or manganese, sufficient chloridization should be effected in the tube mill to form the necessary iron chloride which, on later decomposition in the roasting furnace, will furnish the necessary chlorine to cause the chloridization of the metals sought.

It is evident that the sulphides may be chloridized in two ways, viz., by free chlorine gas directly and by chlorine carried by sulphur monochloride. It is probable that both actions take place in the tube, but just where one action stops and the other begins is subject to question. After the action in the tube is under way there is no evidence to show that chloridization is not entirely effected by the chlorine of the sulphur chloride, and that the chlorine gas admitted to the tube is not first combined with sulphur, the latter acting as a carrier to deliver the chlorine to the metals of the sulphides and then make its exit with the gangue. This proposition leads to the theory that there are zones of chloridization in the tube, the positions of which are subject to shifting brought about by the adjustment of supplies of ore and chlorine.

By a proper regulation of the ore and gas supplies, and the addition of air, the temperature due to chemical reaction can be controlled. After this partial chloridization in the tube mill, the ore is conveyed to a roasting furnace, preferably of the multiple-hearth type. Here the partially chloridized ore is subjected to the action of heat, furnished by the burning sulphur or supplied from an external source. The heat decomposes the iron and similar chlorides and liberates chlorine, either free or as hydrochloric acid, leaving the metals of the decomposed salts in an inert oxide condition. The chlorine or hydrochloric acid liberated unites with the sulphides or oxides of silver, copper, lead and zinc, forming chlorides of these metals.

In order to produce the desired action, the chloridizing agents should be in excess, and means are provided, therefore, for the collection of chlorine gas escaping from the main chloridizing hearths of the furnace. One way of effectively conserving the excess chlorine is to pass the furnace gases containing this element through a bed of sulphide ore. In the use of a six-hearth furnace as shown in the diagram, the ore from the tube mill is fed into hearth No. 3 and progresses downward. Hearths Nos. 1 and 2 are supplied with raw sulphide ore which circulates through these hearths. The gases enter these two upper hearths from the lower or main chloridizing hearths, and filtering through the sulphide ore pass to the stack. A portion of the ore from the two upper hearths is by-passed to hearth No. 3, the quantity depending on the rate of absorption of chlorine by the raw sulphide ore.

### Solution of the Chloridized Metals

The ore thus treated in the furnace is passed to an agitator to which water or mill solution is added. The heated ore and the heat evolved by the process of solution is sufficient to make possible the solution of such chlorides as lead and silver. Chlorine may be added at this point if found necessary to bring the gold into solution. From the agitator, in which all the metals go into solution as chlorides, the pulp is treated in properly designed filters where the gangue, ordinarily consisting of silica, sulphur and the oxides of iron and manganese, is retained.

The combination of a mechanical agitator and blowcase has proved most effective in accomplishing solution of the chlorides. This apparatus is constructed of impregnated wood like a large barrel. When solution is complete, steam is admitted which forces the pulp through the filter; and by forcing steam through the residue after the solution had been removed, a highly efficient wash is obtained with a minimum of water. The filtering medium is asbestos cloth. The filter residue may be sluiced over amalgamated plates to recover any gold or silver not dissolved.

### Concentration of Solution and Precipitation of Metals

The further treatment of the solution depends on its metallic content, particularly zinc, and on the burden of the sparingly soluble salts, *e.g.*, $PbCl_2$ and AgCl. The solution is circulated between the weak-solution storage tank and the agitator until its metal contents justify refining, after which it is treated according to the following general scheme. It is first agitated in the presence of metallic copper which precipitates gold and silver. The solution is decanted and agitated with metallic iron to precipitate copper. Lead is then removed by precipitation with metallic zinc; and, if necessary, the solution is treated with zinc oxide, carbonate or silicate, chlorine and sulphur dioxide, to remove iron, manganese or lime. These latter impurities may have existed in the solution on account of insufficient decomposition in the roasting furnace, or may have been introduced in the substitution process described above for the removal of metals. The zinc precipitant for this latter purpose may be either the natural minerals or zinc oxide obtained by the roasting of zinc ores.

### Electrolysis of Fused Zinc Chloride

After the above treatment the solution contains only zinc chloride. It is passed to the vacuum evaporators where the moisture is removed, and then fed to electrolytic cells in a fused condition. Metallic zinc is deposited and chlorine liberated for reuse. The cells are operated at a temperature of about 450 deg. C., and the gas escapes at approximately the same temperature. It may be passed under the vacuum pans to aid in evaporation and at the same time be cooled to a temperature suitable for use in the tube mill.

The various precipitates of gold, silver, copper and lead are collected separately in filter presses, dried, melted and cast into bars.

### Chemical Data

Practically all the work done on this process hitherto has been directed to obtaining results, and not particularly to chemical interpretation of all the reactions involved. Although conditions apparently are favorable to the formation of sulphates, particularly that of lead in the roaster and agitator, the fact remains that their occurrence has not been observed in any tests. For example, a recent test on an ore containing 6 per cent lead and 3 per cent sulphur yielded an extraction of over 99 per cent lead. This test was run under conditions apparently favorable to the formation of lead sulphate, and yet this did not appear.

The following statements are based upon actual experience with the process. While the metal precipitants in contact with solution are always in excess, the substitution reactions are practically quantitative, as the solution during the refining stage is neutral. Any acidity caused or acquired is utilized in the agitator treatment of the ore from the roaster. The necessary hydrochloric acid is obtained from the decomposition of $S_2Cl_2$ in the dust chamber.

The successive precipitations occur rapidly, and all the precipitants are granular and easily filtered. Owing to the high solubility of most of the chlorides formed, the solutions can be maintained in concentrated condition.

The degree to which ferric chloride is permitted to form and enter solution is determined by the quantity of ore containing oxides, carbonates and silicates which are available for treatment.

The metallic precipitates are freed from any associated metal used as precipitant by washing the precipitate with a solution of its chloride.

The larger the scale on which this process has been applied, the easier has it been to maintain control of the operations; and its application to commercial practice has been anticipated only in the light of "continuous and concurrent operations, where ordinary human beings are a function."

The electrolysis of fused zinc chloride has proved a much more simple operation than the electrolysis of sodium chloride solution. The chlorine loss has been found so low as to be almost negligible as a cost factor. The high efficiency of the zinc chloride cells has established commercial zinc chloride as the source of chlorine for starting operations and for replacing such less as may occur. The ore itself has proved the most satisfactory storage for chlorine.

# Notes on Chemistry and Metallurgy in Great Britain

(*From our Special Correspondent*)

### Cement Testing

Mr. W. L. Gadd recently read a paper before the Concrete Institute which deserves the attention of all who are interested in the testing of cement. His main object was to call attention to the fallacies existing in certain recognized processes of testing, not excepting some of those found in the British Engineering Standards Specification.

First, with regard to time of setting, the author said that the object of exposing the sample spread out to a depth of 3 in. for 24 hours seemed to be partly to cool the cement to a normal temperature, and partly to get it under the conditions similar to those resulting from keeping the cement in sacks or casks for a few weeks. The cooling manifestly could be effected without exposing the cement to the air; and the results of storage were very various.

He made experiments with two large samples of cement, one recently ground and the other ground a month previously, which were put into sacks and taken to warehouses at six different works. Six samples were the produce of rotary kilns and six of chamber kilns. After fourteen days the sacks of cement composing each sample were well mixed, sampled and put aside for a further fourteen days, when another mixture and taking of samples was carried out.

The tests showed that in most cases the time of initial setting was quicker after both fourteen and twenty-eight days; but there were two exceptions, one of which first showed and afterward quickened, and the other quickened and afterward became slow. This went to show that cement kept in sacks in a dry condition might become either slow or quick in time of setting.

He found that the results obtained from samples aerated for twenty-four hours, as laid down by the Engineering Standards Specification, did not agree with those of the bulk sample from which they were taken, and it was demonstrated that the time of setting was affected by the conditions of storage, and although the samples tested varied considerably in composition, they all exhibited erratic behavior in this respect.

Direct experiments with pure dry air showed that this did not affect the setting time; but moist air free from carbon dioxide had a marked effect, while absorption of carbon dioxide was proved to considerably accelerate the setting time.

With regard to sieves for determining the degree of fineness, he had examined many rolls of wire cloth strictly agreeing with standard specification, but yet totally inaccurate for their intended purpose. The real standard should be the size or area of the holes in the sieve; and the diameter of the wire threads and their number per inch were of secondary importance.

The size of the sieve itself also affected the result. A very fine sample he found to leave 3.5 per cent on a large sieve, and 5.6 per cent on a smaller one—a difference of 37 per cent.

The determination of the specific gravity was still laid down in the Standards Specification, but it was not really any indication of a proper degree of calcination, and it depended to a great extent upon the age of the cement, and whether it had absorbed carbon dioxide and water. These were Butler's conclusions, and he entirely agreed with them.

Then, again, certain specifications directed that the specific gravity should be taken after drying the cement at 100 deg. C.; but this was quite useless, because carbon dioxide would not be expelled below 300 deg. C.; and he was of opinion that the only reliable guide in the case of doubtful cements was chemical analysis.

Standard sand was generally supposed to give the best results obtainable with any given sample of cement in respect to tensile and crushing tests; but this view was not correct although the standard sand ensured comparable results. Then, again, different countries used different standard sands, and it had been proved that the crushing resistance of concrete made with the same cement varied with the size as well as with the nature of the aggregate.

The autoclave test was only a revival of Dr. Erdmeyer's high-pressure steam test, which German cement experts had rejected as unreliable and misleading; and the results of American and Canadian research showed no ground for its adoption.

On the question of free lime the author remarked that the view that unsoundness of cement was due to free lime had been strongly held for a long time and was now widely accepted; but the theory that the expansion of cement was due to the presence of free lime was not supported by any authenticated facts. His opinion was that unsoundness was most probably caused by an abnormal silicate, very possibly dicalcium silicate, an unstable compound which disintegrated slowly with resulting increase in volume.

### The Institution of Petroleum Technologists

Last month the guarantors of a fund for the foundation of an Institution of Petroleum Technologists held a meeting for the purpose of establishing this new institution. The desirability of forming such a society has been very apparent during recent years not only for the technologists but for the benefit of all who are engaged in the petroleum industry. The main objects of the institution are the collection and dissemination of reliable information in all branches of petroleum technology; to afford facilities for interchange of ideas on methods of production, refining, transport, storage and uses of petroleum and shale oil and their products; and to insure the attainment of a high standard of efficiency by technologists.

On the proposition of Professor Vivian B. Lewes, seconded by Mr. A. C. Adams, Sir Boverton Redwood was unanimously requested to accept the office of president. After accepting office, Sir Boverton announced that more than seventy applications for membership of the institution had been received.

**Colorado plants** of the A. S. & R. Co. smelted 683,082 tons of ore in 1913, producing 293,836 oz. gold, 13,194,944 oz. silver, 136,247,052 pounds of lead, and 7,119,089 pounds copper. The gross value of the production was $20,996,305.

# Presentation of the Perkin Medal to John W. Hyatt

## Interesting Notes on the Early History of Celluloid, Continuous Water Filtration and Other Inventions of Mr. Hyatt

The eighth impression of the Perkin gold medal for important work in industrial chemistry was presented on January 23 to Mr. John Wesley Hyatt, the inventor of celluloid, continuous water filtration, his roller bearing system, etc., at a joint meeting of the New York Sections of the Society of Chemical Industry, the American Chemical Society, and the American Electrochemical Society.

Mr. Gustave W. Thompson, chairman of the New York section of the Society of Chemical Industry, presided. The meeting was well attended and the occasion most enjoyable.

The chairman, Mr. Thompson, discussed in his introductory speech scientific imagination as the chief faculty required in men up to the mark to become Perkin medalists. The beloved dean of American chemistry, Professor Charles F. Chandler, followed with a record of Mr. Hyatt's life work and formally presented to him the Perkin medal. Mr. Hyatt, sprightly in spite of his seventy-six years, expressed his sincere thanks and gave a most interesting account of the invention of celluloid and a description of his sugar-cane mill. The proceedings were concluded by Dr. Frank Vanderpoel, who gave some delightful personal reminiscenses from his association of many years with Mr. Hyatt.

JOHN WESLEY HYATT

### Chairman's Address

The opening address was made by the chairman, Gustave W. Thompson. After some brief remarks on the origin of the Perkin medal, he continued:

"The medal is awarded for valuable work in applied chemistry. Whatever the future may have as interpreting the grounds for merit, in the past it has generally been considered that this work should be in the nature of original or inventive work which has proved of great public value. The question I would propound to you to-night is: What is the mental faculty which has made the recipients of the Perkin medal what they are? In what respect do these men differ from their fellow chemists, which has enabled them to be so successful in the application of chemistry to the arts? * * *

"In 1870, Tyndall delivered his famous discourse on the 'Scientific Use of the Imagination.' In this discourse he showed the value of the imagination properly made use of in solving some of the most difficult problems of physics. Tyndall has shown us how the imaginative mind, seeing resemblances in things, can supply the missing parts in such resemblances, those missing parts being hidden from the senses.

"It was this power of the imagination which enabled Kekule to lay the basis for the working out of the structure of many complex organic compounds, which work has been of incalculable benefit to chemical science and industry, and thousands of instances could be given showing that practically all of the progress made in the science of chemistry has been due to this proper use of the imagination; but considering the work done in applied chemistry, we see clearly that it was the imagination of Herreshoff that enabled him to develop the metallurgy of copper, and of Behr in his work on the separation of the oil contained in the germs of corn, and of Acheson, who saw in his imagination that, if flocculating agents existed, there were probably also *de*-flocculating agents, and of Hall, who believed that somewhere there was a solvent for alumina, from which aluminium could be obtained electrolytically, and of Frasch, who saw in the oil and salt wells the suggestion of the possibility of recovering sulphur from the bowels of the earth, and of Gayley, who saw the possibility of the dry blast in increasing the output and decreasing the cost of the blast furnace—and tonight, in the case of Hyatt, who saw in the drop of dried collodion the possibility of producing a plastic mass, which was finally obtained in celluloid.

"It was Tyndall who emphasized the extreme value of the two little words 'as if' when used by the scientific mind, showing how, from things seen, a scientific imagination can lay bare things unseen and make possible discoveries of great value. Discoveries often come by accident, but it is the imaginative mind that sees in these discoveries future possibilities. It is the imaginative mind which, following out discoveries so made, is led into unlimited fields of usefulness. We must not think, however, of imagination as being the sole factor, although it is probably the principal factor, in the production of valuable works. There must be energy, concentration and persistence, which will carry such a mind across the Jordan into the promised land. Nevertheless, the imagination is the most important factor here, because, without it, there would be no promised land.

"As we look around about us upon those with whom we are intimate, we see this imaginative faculty in all degrees of development, and I have this work of suggestion to offer: Those of us here who are educators, in whose hands are being moulded the minds of future chemists, should we not ask them whether the work which they are doing tends to develop this imaginative faculty, or whether it is indeed possible for them to sow in the minds of their students the seeds of imagination if they do not already exist there?

"It seems to me that there is no better place, no better occasion, than this place and this occasion, when we are honoring, by the presentation of the Perkin medal, a man in whom the imaginative faculty was highly developed, to put before you the need of the imaginative faculty in as emphatic a manner as possible and to urge that in our educational institutions this faculty should be developed to the highest degree, for, if we are honoring Mr. Hyatt on account of his possession of this faculty, should we not seek to increase the number of those who possess the faculty in a high degree? Is not the real purpose of the Perkin medal something more than the honoring of its recipients—great as that purpose is—is it not for the purpose of encouraging those faculties on which the presentation of this medal rests?"

### Presentation Speech by Dr. Chandler

Professor Chandler in his official presentation speech first gave a brief account of Mr. Hyatt's early life.

"Mr. Hyatt was born at Starkey, Yates County, New York, in November, 1837. He was aducated in the public school and later in the Eddytown Seminary, where he excelled in mathematics.

"In his early boyhood he acquired a strong taste for mechanical affairs in his father's blacksmith shop. In his sixteenth year he went to Illinois and learned the printing business, working at this trade for the following ten years. . . .

"He then went to Albany and worked as a journeyman printer for about two years. Seeing a $10,000 offer for a substitute for ivory for billiard balls by Phelan & Collander, of New York, he began experimenting nights and Sundays in the hope of gaining the reward. He made a number of useful plastic compositions, none of them, however, good enough for billiard balls, but he started to make checkers and dominos of pressed wood, and with his two brothers established what is now the Embossing Company, of Albany, N. Y., which has been a highly successful concern for more than 40 years, under the mechanical management of Mr. Hyatt's younger brother, C. M. Hyatt.

"In 1870 he invented and patented a machine for turning billiard balls, by which an unskilled workman can do as much as a dozen skilled workmen could accomplish by former methods, securing at the same time perfect accuracy.

#### THE INVENTION OF CELLULOID

"His attention having been called to the character of the solid nitrocellulose left by the evaporation of liquid collodion or artificial skin, as it was called when collodion was first put upon the market for covering cuts and other wounds, he turned his attention to the subject of nitrocellulose as a suitable material for producing plastics. It should be remembered that gun cotton, or nitrocellulose, was first discovered by Schoenbein in 1845. In 1847 Maynard announced the discovery that while nitrocellulose is not soluble either in alcohol or ether alone, it is soluble in a mixture of the two, and he gave the name collodion to the solution, which has since found its way very extensively into medical use. It also served to solve the problem of producing photographic pictures, either positives or negatives, upon glass, practically sounding a death knell for the beautiful though troublesome daguerreotype process. The wet collodion process was introduced by Scott Archer in 1851.

"Hyatt was entirely ignorant of the various efforts which had been made by Parks, Spill and others to utilize soluble nitrocellulose or pyroxyline for the manufacture of plastic materials, and consequently he started out without any hints or suggestions as to how he should proceed. His first success resulted in the manufacture of billiard balls by first making a solid core of another plastic material and covering the same with nitrocellulose dissolved usually in ether and alcohol. The process was so successful that a good business was established in 1870.

"In the meantime Hyatt invented celluloid and began the manufacture of celluloid and bone dust billiard and pool balls. At this time his brother, Isaiah S. Hyatt, joined him, and they worked together until the brother died in March, 1885.

"I do not propose to give a detailed history of the progress made by Mr. Hyatt and his brother in establishing the celluloid industry. I will merely remark that Hyatt's patent 88,633, dated April 6, 1869, was for a molding composition to imitate ivory and other substances composed of fibrous material and gum shellac or other solid fusible adhesive gum.

"His patent No. 88,634, dated April 6, 1869, was for an improved method of coating billiard balls, consisting in dipping the billiard balls made of some suitable composition into a solution of collodion which might be given any desired color beforehand.

"His patent 89,582, dated May 4, 1869, was for a composition consisting of ivory dust or its equivalent mixed with collodion and subjected to pressure during the evaporation of the solvent.

"His patent 91,341, dated June 15, 1869, taken out by the two brothers jointly, was for manufacturing solid collodion with very small quantities of the solvent dissolving the pyroxyline under heavy pressure, thus securing great economy of solvents and a saving of time.

"Their patent 105,338, dated July 12, 1870, shows the fundamental invention of celluloid. It is entitled Improvement in Treating and Molding Pyroxyline. The three claims of the original patent are:

"1. Grinding pyroxyline into a pulp, as and for the purpose described.

"2. The use of finely comminuted camphor-gum mixed with pyroxyline pulp, and rendered a solvent thereof by the application of heat, substantially as described.

"3. In conjunction with such use of camphor-gum, the employment of pressure, and continuing the same until the mold and contents are cooled, substantially as described.

"This patent was reissued three times in order to avoid ambiguities. The claims of the last reissue are as follows:

"1. The use of finely comminuted camphor-gum mixed with pyroxyline pulp, and rendered a solvent thereof by the application of heat, substantially as described.

"2. In conjunction with such use of camphor-gum, the employment of pressure, and continuing the same until the mold and contents are cooled, substantially as described.

"The specification fixes the proportion of about 1 part of camphor to 2 parts of pyroxyline. Modifications of this process were embodied later in U. S. patents 156,352 and 156,353.

"From this time on celluloid became a most important plastic, superior in almost every respect to any other plastic hitherto proposed, for the manufacture of the greatest variety of articles useful and ornamental.

"Seventy-five different patents were taken out either by John Wesley Hyatt alone or in association with his brother, Isaiah S. Hyatt, and an enormous establishment grew up at Newark in the hands of the Celluloid Company."

Professor Chandler then mentioned that in one of the most important and recent works on applied chemistry he found the statement that celluloid "was first produced by Daniel Spill, of Hackney, England, and came into commerce under the name of xylonite. Spill's method of converting the nitrocellulose has been followed for more than forty years."

Professor Chandler emphasized that there was no logical ground for making that statement. Celluloid was invented by the brothers Hyatt and not by anyone else.

It is quite true that many other experimenters sought to prepare useful plastic compounds with the aid of pyroxyline prior to the Hyatt invention of celluloid. But no one succeeded in producing anything like celluloid. Professor Chandler proved his point by a careful and detailed analysis of the patents of Alexander Parks and Daniell Spill, and showed that Spill, in his British patent 1739 of May 11, 1875 (nearly five years after Hyatt's collodion patent) made no reference to any material that could possibly be called celluloid. This whole matter has been threshed out in the Federal courts as long ago as 1886, and the Hyatt patents have been sustained, although everything that had been patented or published was carefully studied and discussed during the litigation.

### OTHER INVENTIONS

"Mr. Hyatt's activities were not limited to celluloid. Among his other inventions also of great importance we find a *sugar cane mill*, very superior to any mill previously used in its efficiency, both in increasing the percentage of juice extracted from the cane and greatly diminishing the time necessary to extract it, and giving a higher value to the refuse bagasse as fuel.

"In the early 80's Mr. Hyatt and his brother Isaiah took up the subject of *water filtration* and started a company called the Hyatt Pure Water Company. Isaiah Hyatt invented and patented a very important feature of the filtration process February 19, 1884, Patent 293,740. It marks the beginning of a new era in water purification. Coagulants had been previously used to purify water, but the difficulty was that the water was held in large tanks or cisterns. The coagulant was added to it, the whole was thoroughly agitated and then it was necessary to allow it to stand 12 to 24 hours for the coagulum to settle to the bottom. The Hyatts conceived the idea of employing a coagulant which could be added to the water while it is on the way to the filter, so that no large settling tanks or basins are required and no time is lost. The claim of this patent is as follows:

"The method herein described of arresting and removing the impurities from water during an uninterrupted passage of the same from a supply pipe into a filtering apparatus, thence through a filter bed contained therein and out through a delivery pipe leading therefrom, which method consists in introducing into the water simultaneously with its passage to or into the filter a substance which will sufficiently coagulate or separate the impurities to facilitate their arrest and removal by the filter bed, thus obviating the necessity of employing settling basins.

"I was connected with a litigation which followed the issue of this patent, and studied the process and apparatus at Somerville, N. J., Niagara Falls and Elmira. The process was unusually successful. At Somerville the river water exhibited a milky opalescence caused by such fine particles of clay that no filter would clarify it. By a proper attachment of an alum box to the feed pipe to the filter, a minute quantity of alum was added to the stream of water on its way to the filter, less than one grain to the gallon and in the few seconds that elapsed before the water reached the filter bed of the ingeniously constructed Hyatt filter, coagulation had taken place and the coagulum, including the alumina of the alum and the clay, bacteria and other suspended impurities of the water, had been converted into such flocks as made it possible for the bed of sand in the filter to arrest it completely. These Hyatt filters are so constructed, whether they are on a large scale or small scale, that they can be washed completely at any convenient moment by simply reversing the current through the filter. This churns up the sand and separates from it the accumulated coagulum.

"Nearly all the paper mills and woolen mills in the country were and still are supplied with these filters, as are also more than 100 cities and towns.

"The validity of the patent was established through law suits which were brought against the city of Elmira and the city of Niagara Falls. In 1891-2 Mr. Hyatt took up the subject of *antifriction roller bearings* with great success.

"I think that the facts to which I have called your attention, although very briefly expressed, will satisfy you of the great achievements of Mr. Hyatt and will fully justify your committee in placing Mr. Hyatt beside Sir William Henry Perkin and the six American chemists who have already received the Perkin medal.

"It gives me great pleasure, as the representative of the Society of Chemical Industry, and the affiliated chemical and electrochemical societies, to place in your hands, Mr. Hyatt, this beautiful token of the appreciation and affection of your fellow chemists."

## Mr. Hyatt's Speech of Acceptance

Mr. Hyatt spoke as follows:

"I have never looked forward to any such honors as you have bestowed upon me, and I do not know how fittingly to express my gratitude. You have overlooked my lack of early training in the sciences with which you are all familiar, and only look to results which have been obtained mainly by persistent and, many times mistaken, experiments. Some successful experiments I might never have made if I had been familiar with the danger theories of some learned men.

### THE INVENTION OF CELLULOID

"From my earliest experiments in nitrocellulose, incited by accidentally finding a dried bit of collodion the size and thickness of my thumb nail, and by my very earnest efforts to find a substitute for ivory billiard balls, it was apparent that a semi-liquid solution of nitrocellulose, three-fourths of the bulk of which was a volatile liquid while the final solid was less than one-fourth the mass of the original mixture, was far from being adapted to the manufacture of solid articles, and that I must initially produce a solid solution by mechanical means.

"The only useful solvent known to me at that time was a mixture of alcohol and sulphuric ether; with the old formula (about equal parts of ether and alcohol) I mixed in a closed mill a thick paste of soluble cotton, made by the old firm of Charles Cooper & Co. After mixing, the cover of the mill was removed and the mass evaporated down to a thick dough, which was then forced accurately around the ball (made of another substance), and allowed to dry.

"This I found resulted in a rather brittle coating, owing, as I found, to the unequal evaporation, leaving only the alcohol, a poor solvent by itself, at the final shrinkage. This was remedied by using only the least amount of alcohol (five parts ether to one alcohol) necessary as a solvent. Even this coating shrunk to less than half of its original thickness and required to be dried immersed in water under several hundred pounds' pressure per square inch to insure its solidity and freedom from bubbles. It became necessary to strain the mass by forcing it through a very fine sieve to exclude the unnitrated fibers.

"All these difficulties stood in the way of success, except in high-priced articles like billiard balls. Other seriously objectionable features became apparent. In order to secure strength and beauty only coloring pigments were added, and in the least quantity; consequently a lighted cigar applied would at once result in a serious flame, and occasionally the violent contact of the balls would produce a mild explosion like a percussion guncap. We had a letter from a billiard saloon proprietor in Colorado, mentioning this fact and saying he did not care so much about it, but that instantly every man in the room pulled a gun.

"I next had a small beating engine made, to pulp the nitrocellulose. In one experiment I placed a small quantity of this dried pulp in a strong cylinder and forced quickly a minimum quantity of liquid solvent into it with high pressure. The result was a solid substance, as hard as sole-leather, which soon dried, leaving a fine hard disc about three-fourths of an inch in diameter and one-half an inch thick. While no explosion ever resulted from this, there was real danger to be feared, and the matter was dropped.

"My brother, I. S. Hyatt, joined with me at that time, and finding it stated in some patents to which I was referred, that a little camphor added to the liquid solvent was beneficial, we conceived the idea that it might be possible to mechanically mix solvents with the pulp and coloring matter while wet, then absorbing the moisture by blotting papers under pressure, and finally submitting the mass to heat and pressure.

"To our surprise, we noticed a slightly solvent action of the precipitated and washed camphor upon the pulp, even before the heat and pressure, and without other solvent we succeeded in producing a transparent slab one-fourth of an inch thick, fine, and as hard as wood.

"My brother took some samples to the American Hard Rubber Company, with the view of interesting them. They employed the late Professor Charles A. Seeley, who had made collodion for the government during the Civil War, to investigate the matter. He came to our place in Albany, N. Y., and we conducted the whole process for his inspection, very successfully. He remarked that he had come prepared to detect some chicanery, but could see no deception, and expressed himself as satisfied. He kindly advised us that if, accidentally or otherwise, we were to apply a little too high temperature, the quantity we were dealing with would inevitably destroy us with the building and adjacent property. While we did not accept this as true, it was disturbing.

"The following day between 12 and 1, when all were out, I rigged up a four-inch plank used as a vise-bench, braced it between the floor and ceiling, between the hydraulic press and the hand pump, intending it to shield me from possible harm. I then prepared the mould, heating it to about 500 degrees Fahrenheit, knowing it would certainly ignite the nitrocellulose and camphor, and would abide by the result. The gases hissed sharply out through the joints of the mold, filling the room with the pungent smoke. The mold, press, building and contents were there, including myself, very glad that I did not know as much as the professor.

"The next step was to make a small stuffing machine, consisting of a cylinder, four-inch bore, about a foot long, terminating in a tube three-fourths of an inch bore, ten inches long, immersed in an open oil-jacket, with a gasburner and thermometer. A capnut with one and one-fourth inch screw forced a plunger upon the cakes of incipient celluloid, which were heated at the outlet end of the cylinder passing through the heated tube into molds, and also through nozzles forming rods, tubes, etc.

"We found it advisable to lower the melting point of the camphor by adding a small quantity of alcohol or other solvent of camphor. A much larger hydraulic stuffing machine was then made. Dental plate blanks were the principal part of our early business.

"My brother interested some New York capitalists —principally composed of General Marshall Lefferts, Joseph Larocque and Tracey R. Edson—and we removed to Newark, N. J., in the winter of 1872-73. We had nearly all the appliances and machinery to design and build, which progressed with some halts and mistakes for two or three years, when a fire occurred in our four-story and basement building, utterly destroying all our stock and machinery, and pushing out the whole front of the building (which was very weak), and severely injuring several of our men, who all finally recovered, although one—Mr. Charles S. Lockwood—was in great danger for a long time. We then started our present works, acquiring knowledge and experience, my brother starting a separate factory for making brushes, mirrors and combs. Early in 1878 my brother went to Paris and started the French Celluloid Company.

"Before we left Albany we began the use of tissue paper in place of carded cotton or bleached flax, which finally resulted in getting tissue paper of definite thickness and materials, and breaking it up into small separate pieces by a machine I constructed, drying these separate pieces in a loose mass and nitrating them instead of the carded cotton.

"In 1876 I was allowed to employ a chemist for determining our acids and to systematize our nitration, instead of merely using hydrometers and thermometers, and Mr. Frank Vanderpoel was selected by me. So far as I know, the analyses of mixed spent acids was not reduced to practical work. Professor Seely proposed that we separate the nitric and sulphuric acids by distillation, and then bring these to the proper strength before mixing, which was not adopted. Vanderpoel first removed the gelatinous flock by adding finely powdered natural barium sulphate and allowing the barium and flock to subside, which was a great success. I had previously tried filtration, which was impractical.

"After much labor Vanderpoel perfected a quick and accurate method of determination of the spent acids, and then added the required fresh acids. An elaborate and extensive battery of tanks was constructed, the acids being moved through copper pipes, where required, by means of air pressure. The tanks for mixing the comminuted tissue paper with the prepared acids were arranged on a turntable supporting a dozen or more tanks, each holding hundreds of pounds. A rotating stirrer was arranged to stir in the requisite amount of paper in one tank, the turntable being revolved to the next tank, and so on. At a distance embracing about half a dozen tanks from the stirrer was located a centrifugal machine, which separated out most of the acids. The nitrated paper was then thrown into a washing device, and the partly washed paper then fell into large tanks of fresh water and was thoroughly washed. A very considerable number of tons of paper per day were and are treated in this way.

"The next procedure was to grind this nitrated paper in a beating engine. The water was then mainly removed by a centrifugal machine. The mixture of pigments camphor and nitrocellulose was then made, according to the results required, and ground together in a mill, then pressed into slabs or cakes, and still further deprived of moisture by great pressure, and finally deprived entirely of moisture by blotting papers repeatedly changed. These cakes are then broken up and alcohol or other desired solvents added and allowed to soak in. The partly dissolved mass is then masticated in heated rolls, turned out into necessarily rough sheets, is cut into strips and rolled up into cylinders, ready for the stuffing machine.

"The great want was to furnish celluloid in solid perfect sheets, and this neither the rolls nor the stuffing machines could possibly do, with all our experience. I constructed a special nozzle for the stuffing machine, to form a slab about one and one-half inches thick, seven inches wide and several feet long, which was pressed between steam plates, one of them with undercut grooves, to hold the slab. A machine was made with shaving knife and reciprocating bed, and by it the slab was shaved into sheets of the desired thickness. These slabs were necessarily imperfect, and were too small. After showing this result to the other directors, I proposed building a hydraulic pressure steam-heated mold, to make a slab or block about two feet by five, and three inches thick, in which to weld and press a pile of rough sheets from the masticating rolls.

"General Lefferts, our much-beloved president, had suddenly died a year or more before. To those who knew the least about celluloid my suggestion looked pretty good, but to others came a great fear of possible danger and failure to weld up such a mass. At last they gave me authority to build the apparatus, limiting me to less than half its cost if fairly estimated. With this authority, which consisted more of the privilege of trying such an apparatus than in providing for its cost, I ordered the machine, agreeing to pay the machinist all above the appropriation if it failed to work.

"The machine was built and most carefully tried in the presence of only the new president, who knew little about celluloid, and Mr. Stevens and Mr. Lockwood among the employees. The mold was cooled and opened, and nice sheets were at once made, considering that only scrap material was used, though less than half the block was welded. This meant reheating, which was at once done, and the whole was known to be a success.

"I dwell upon this because of its vast importance to us. It multiplied the value of celluloid many times, making a much stronger and finer material than was produced by the former means.

"About this time we were enjoined from bleaching the iron out of the pulp, caused by the iron-beating knives, and it was up to me to remedy the serious difficulty. A large revolving drum of copper, through the axis of which was a shaft with beating arms rotating at a very high speed, in which the mixture of nitrated paper, camphor and pigments was placed, and the whole beaten to a pulp without the discoloration of the iron and water, and without the loss in washing and bleaching the fine pulp from the beating engine.

"In order to clearly differentiate my work in celluloid from that of others in the nitrocellulose industry, I will summarize as briefly as I can:

"First, the idea of combining with the nitrocellulose only the exact or approximate amount of solvent required for a solid solution. This required a nearly perfect mechanical mixture before very much solvent action could take place.

"Second, completing the solution by means of heat and pressure.

"Third, eliminating the practically unnitrated fibers by pulping.

"Fourth, employing tissue paper in place of carded fiber.

"Fifth, avoiding the terrible danger of drying out the moisture by exposure in drying room.

"Many years ago I patented the process of first pressing out all the water possible and displacing the remainder by forcing alcohol through under pressure. This, I understand, is now used by other nitrocellulose workers, but we prefer the method herein described.

"Sixth, the stuffing machine process.

"Seventh, the sheeting process, most essential.

"Mr. Stevens has been with me ever since he was fourteen years old, and has invented solvents and many other things of great importance in the art, and stands at the head of nitrocellulose workers at the present time.

"Mr. Harrison, in his department, has invented the method of imitating the grain of ivory, of smoked pearl, of onyx, and of many other beautiful colors and effects. He has been with us nearly forty years. Others are entitled to much credit, but it is impossible to name them here."

Mr. Hyatt then gave a description of his sugar-cane mill, an account of which is reserved for a later issue. Mr. Hyatt concluded as follows:[*]

"I have taken out 238 patents (a few of them being joint inventions with others), and several new industries have resulted. The one of next importance to celluloid is named The Hyatt Roller Bearing Co. I have received considerable liquid money, most of it having been of a volatile and inflammable nature. Age ought to bring wisdom."

### Dr. Vanderpoel's Reminiscences

Dr. Frank Vanderpoel began his remarks with a personal tribute of affection to Dr. Chandler and Mr. Hyatt. He became Mr. Hyatt's chemist three years after he had left Columbia University.

"To refer to the early days of the celluloid business in Newark, there seemed to be a good deal of prejudice against it in that city. On account of an unfortunate fire which took place there shortly after the company began operations, the people of Newark did not, as a rule, take kindly to a material which was reported as being made of gun-cotton and camphor. Of course, a statement like this would never lose in transmission, and the public would look askance at any article of commerce which contained as an ingredient this high explosive. I remember a story told of a man who happened to touch, with a lighted match, one of a pair of cuffs made of celluloid when, to his amazement there was a terrible explosion, and he barely escaped with his life—or words to that effect.

"Well, this and other stories of a like nature produced a strong feeling against the manufacture of this new substance, to say nothing of its use by the public and, of course, some one had to bear the brunt of it. Naturally, the inventors (the Hyatt brothers) and those most intimately associated with them in business, had to carry the burden; and it wasn't a very light one either. But our friend had the enthusiasm of the inventor, an enthusiasm which he imparted to those who were associated with him, and without which success would have been long delayed, if not impossible.

"I suppose that, in the minds of some, even at the present day, the idea exists that the principal ingredient in the material referred to is true gun-cotton, the highly nitrated compound of cellulose. This is because the public, as a rule, is not given to distinguishing between the compositions of different chemical compounds. If, in order to make true gun-cotton, you treat cotton fibre with a bath composed of a mixture of strong sulphuric and nitric acids, why, it stands to reason—so some of these people think—that cotton fibre treated with a bath of these same acids, no matter what their percentage composition may be, will be converted into the explosive compound. You know that this is not the case, but the general public does not, or did not, some thirty years ago.

"Shortly after I became associated with the celluloid company, samples were made of these two varieties in nitro-cellulose, using raw cotton fibre in each case, and their solubility tested in a strong solvent, and thus compared. Any nitro-cellulose which would not dissolve in this solvent would be utterly worthless as a basis for the manufacture of our product.

---

[*] Mr. Hyatt told informally a little story which, while not included in his official address, is too characteristic to omit it from this report. An employee of his of many years—a foreigner who had never learned to talk correct United States, in spite of his other abilities—came to die. Said he: "Me now die. John Hyatt die some day too. Perhaps me go hell. Me don't care. John Hyatt build ice machine"

"Upon making the test, the fibres of the lower nitrated compound disappeared in the solution upon the instant that they touched the solvent. This was the variety of the nitro-cellulose which was the principal ingredient in the manufacture of celluloid. How long do you suppose it took the other, the true gun-cotton or tri-nitro-cellulose (or, as some call it, hexa-nitro-cellulose) to dissolve? It was kept in the bottle of solvent for more than six years without showing the slightest evidence of a solvent action—each fibre standing up bravely—then it was thrown away. But the public didn't know of this difference and thought that the product of our friend's brain was a menace to every one who came near it. Prejudice will go a great way, and it takes courage and pluck to fight it.

"Mr. Hyatt's share in the work of making celluloid did not consist in merely getting out the various patents and handing them over to the company. He was often at the works, superintending, advising, assisting in the manufacture, and always on call if things needed his attention. We all felt confidence in his judgment and found afterwards that this confidence was not misplaced.

"The inventor's enthusiasm is a valuable asset or adjunct in the matter of bolstering up the faint-hearted employee who may sometimes think that he has an idea of his own which he would like to have exploited. I think that more than one of the men employed at the works received encouragement from our friend, Mr. Hyatt, in certain lines of work in which they were engaged and which they might have been inclined to give up if it had not been for his enthusiasm and optimism. It not infrequently happens, in this world, that the success which a naturally timid person achieves is due, in some degree, to the encouragement which he may receive from one who has more courage and backbone. As the boys would say, "He doesn't get cold feet," and this means the difference between success and failure. We sometimes need optimistic friends who will help us over the rough places, or the thin ice—put it whichever way you will. Mr. Hyatt was one of these.

"This comforting way of looking at things does not mean, let me say, that everything that a fellow would think of, and suggest, would be endorsed by him. I well remember a remark made by him one day when he had occasion to relate how a certain so-called or self-styled chemist had utterly failed in the solution of a problem which he was absolutely certain he could solve. In fact, he claimed to have solved it some time before, but when a second attempt was made, the result was not in the least satisfactory. "Yes," said Mr. Hyatt, "A man may say to you, 'if I put this brick which I have here on this side of the street with that one over across the way, I'll have two bricks'; but when he goes across the street he finds what he saw on the other side was not a brick, after all!"

"Very likely Mr. Hyatt does not remember this occurrence, but I assure you it is true as is also another one which happened at the works and illustrated his practical way of looking at things.

"You know it is just as important, sometimes to know what to omit doing as to know what to do; what to leave out of your invention as well as what to put into it. A mutual acquaintance, an employee of one of the branches of the celluloid company, went to our friend one day and told him of an invention which he had almost worked out in his mind, and asked his opinion of its value. He was going to make billiard balls out of celluloid, these balls to have a hollow center, and this small cavity was to be partly filled with mercury which, when the ball was struck, would act as a sort of break on the motion of the ball, and cause it to slow down. Mr. Hyatt's reply was, 'Well, if billiard balls came ready-made and partly filled with mercury as you suggest, and you could find some way of getting that mercury out, I think it would be a fine thing.'

"There was one element in our friend's makeup concerning which I cannot speak too highly, for the reason that you don't find it anywhere. In fact, I believe it to be the exception and not the rule. It was his willingness to give every one credit for his own idea and not attempt to appropriate it himself. Sometimes he went further than this; he would take the thought that you gave him, enlarge upon it, or improve it, and then hand it back to you as your own. How many do that today? I think that if you counted them on your fingers, you'd have some fingers left over when you had gotten through counting. . . . There is another quality or characteristic possessed by the successful inventor which is a most important asset. Something which happened not very long ago on a train running across the Arizona desert may, in a slight degree, illustrate the point. The day was hot and dusty, and anybody who has ever traveled those alkali deserts with nothing much in the way of vegetation but sage brush in sight, can tell you what that means. It is decidedly uncomfortable, to say the least, and you look in vain for a cool spot where your eyes may rest—a clump of trees, or a little running water.

"One of the passengers kept looking out of the window every minute or two, pulling the shade to one side as he did so, and then letting it drop back again into place. Another passenger, noticing the interested look on his face asked him what he saw. 'I see miles and miles of corn, acres of wheat and cotton and the whole country covered with farms,' he said. 'When the supply of water back of the tops of those mountains is tapped and brought down here to this prairie, we shall have it blossoming as the rose.' What is your name, the other passenger asked. 'Luther Burbank,' was the reply.

"Now what shall we call this quality or element in the composition of the successful inventor and advanced thinker along these lines? Some might say, 'efficiency.' Well, that is a good name for it. It means making two, three or twenty corn stalks grow where none, or at the most, only one grew before. It means causing the dry desert to become a veritable garden. It means taking a product of the laboratory which before had been only a chemical curiosity, and working upon it in such a fashion, and with such determination that it shall become a most useful article of commerce which shall find application in a multitude of ways and bring comfort, yes, and happiness to many a home."

---

**Gold in Canal Zone streams** has been investigated by the official geologist for the Isthmian Canal Commission, who reports that in no instance has the metal been found in quantities that would justify its recovery. Many samples were washed, yielding from a color or two up to 2½ cents per cubic yard.

**Dressing Copper Plates.**—A correspondent of the *South African Mining Journal* states that he has found a simple remedy for discoloration and greasy scum on amalgamating plates. In the dressing process he has discarded brushes and adopted chamois leather or Hessian sacking. In his opinion the brushes merely mix the scum with the amalgam, while the leather or sacking actually removes it. Since the adoption of this process the plates in the correspondent's mill are in excellent shape.

# Synopsis of Recent Chemical and Metallurgical Literature

## Gold and Silver

**Volatilization of Metals as Chlorides.**—In our issues for April and May, 1913, pages 220 and 230 respectively, mention was made of the process of treating sulphide ores with salt and volatilizing metal chlorides at a high temperature. This process was brought out originally by Pohle and Croasdale in the United States fifteen years ago, but was again discovered last year by Mr. Ben Howe, of Australia. In the issue of the *Mining Magazine* for December, 1913, Mr. Howe gives personally the results of his original investigations and the later tests which he made on a large scale at the Gwalia Consolidated mine in Western Australia. His work came to an unsuccessful end mainly, as he believes, because of unfavorable financial and local conditions; but it is interesting to note that he encountered the same difficulties that Pohle and Croasdale were unable to overcome years ago. In fact, Mr. Howe has stopped just where the earlier investigators left the process; and it is unfortunate that he could not have known of their work so that he could have conserved his funds and started with full knowledge of previous experience.

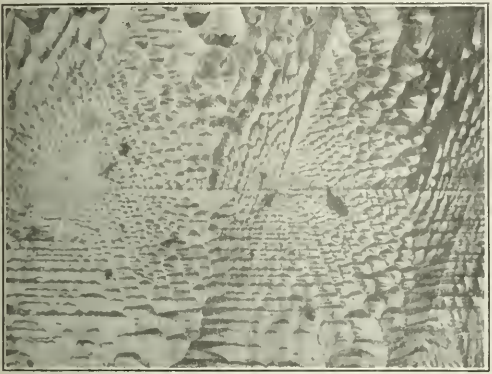

FIG. 1—PURE SILVER

The ore at the Gwalia Consolidated contains gold to the value of $9 or $10 per ton. Conditions of mining are favorable, but the metallurgy is difficult. The ore is a silicate of alumina, with quartz and calcite, containing sulphides of iron, arsenic and antimony. The mineral is finely disseminated through the gangue, and consequently mechanical concentration has proved a failure. Cyanidation after roasting yields only 75% recovery. Mr. Howe turned his attention to volatilization as a possible means of treatment, and met with some degree of success. In brief, the process consists in mixing the ore with salt, roasting at a temperature of about 1000 deg. C., volatilizing the gold as chloride, and recovering it in settling chambers and solutions as an amorphous powder.

Mr. Howe's difficulty centered in the absorption or condensation problem, and it is probable that he would have been impressed with this more quickly had he been trying to volatilize and condense chlorides of base metals such as copper. Having only gold in his ore, the problem was simpler. After allowing the fume to condense in chambers by reducing the velocity of the gases by expansion, and by providing baffles in the form of rods or wires such as are used in smelting works in this country, the gas was drawn through a series of absorption boxes by means of a vacuum pump giving a vacuum of from 1½ to 4 in. mercury. The vacuum boxes were arranged like zinc boxes in cyanide precipitation, and were filled with broken quartz for the purpose of breaking up the bubbles and exposing a large surface to the water. In a test run lasting 83 hr. Mr. Howe volatilized 92 per cent of the gold and recovered 85.7 per cent.

It was found that a long revolving furnace was best adapted to the work, and that the volatilizing process had been carried on most successfully when the discharged tailing appeared in the form of small fritted balls of gangue. Mr. Howe still has faith in the value of the process in treating certain refractory ores, and believes that the difficulties encountered can be overcome.

**Detection of Platinum Metals in Gold-Silver Cupellation Beads.**—It is well known that the presence of small amounts of the platinum group of metals in gold and silver beads obtained from cupellation causes a crystallization or frosting visible to the naked eye. It has been found, however, by Messrs. C. O. Bannister and G. Patchin that for beads containing less than 1.6 per cent of platinum it is necessary to use the microscope to detect the characteristic appearance of beads containing this metal. Their results, with many microphotographs, are published in *Bulletin No.* 111 of the Inst. of Min. & Met. Four of the microphotographs are reproduced herewith, being Figs. 1, 2, 3 and 4.

The summary of results and conclusions arrived at by the authors is as follows:

1. The microstructure of silver, gold and silver-gold cupellation beads is described and illustrated, and in the silver-gold beads the crystallization of silver and gold is distinctly traced in the structure. The visual appearance of beads composed of equal amounts of gold and silver is shown to be similar to that of beads containing over 1.6 per cent of platinum.

2. It is shown to be possible by simple microscopic examination to detect platinum in cupellation beads when present below 1.6 per cent.—that is to say, when present below the amount necessary to cause crystallization visible to the naked eye.

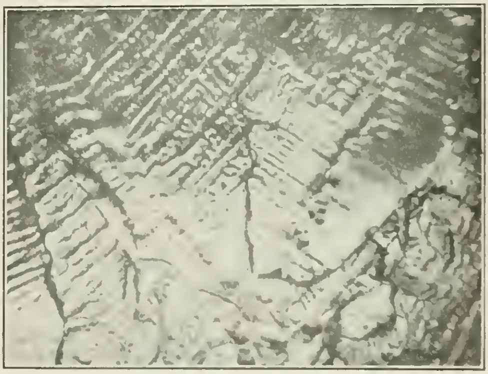

FIG. 2—SILVER (0.4% PLATINUM)

3. The presence of iridium in small quantities can be detected in silver beads by the strained appearance of the crystal caused by internal stresses.

4. The presence of traces of rhodium may be detected by a crystallization of the beads in which the facets of the crystals are distinctly visible. When over 0.03 per cent of rhodium is present this is indi-

cated by a bluish-gray color and a large amount of spitting.

5. Ruthenium is indicated in cupellation beads by a black crystalline deposit firmly attached to the bottom edge of the beads, and in the experiments carried out was always associated with a herringbone-like structure when examined by the microscope.

6. Palladium causes a structure similar to that found in the presence of platinum, but yields satisfactory evidence of its presence by coloration of the parting acid.

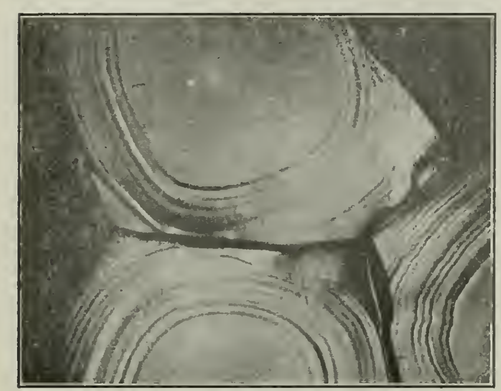

FIG. 3—PURE GOLD

7. No specific indications of the presence of osmium are afforded by the tests made.

8. The indications in the presence of iridium are found to apply equally well to osmiridium.

## Copper, Zinc and Tin

**Monolithic Magnetite Linings for Basic Copper Converters.**—Within the past few years the practice of converting copper matte in converters lined with magnesite brick has become almost universal and has practically displaced acid converting. The usual practice is to line a shell with magnesite brick varying from 9 to 30 in. in thickness in different parts of the shell, according to the severity of the chemical action. Sooner or later the lining spawls and cracks, owing to variations in temperature, and the lining must be renewed. The artificial production of a monolithic magnetite lining or coating over the magnesite brick is the subject of a patent granted to Messrs. A. E. Wheeler and M. W. Krecji, and of an article by them in the December *Bulletin* of the A. I. M. E.

This method of protecting a lining is based on the fact that magnetite is formed in artificial magmas, especially when the proportion of silica is low. Any excess iron over that required to combine with the silica is likely to be deposited in the form of magnetite. As the melting point of magnetite is probably not less than 1527 deg. C., and the temperature of the converter rarely goes over 1200 deg. C., it is evident that the lining of magnetite would have a higher melting point than the converter contents. The lining can be formed by blowing 35 per cent. matte for 10 or 15 minutes and then allowing the charge to cool by the addition of more matter. Alternate blowing and cooling, with the addition of more matte, is continued until the charge is blown to white metal. As no silica is added during this operation, magnetite is formed, and it can be observed as a coating over the magnesite lining. After this the converting operation, with added silica, can proceed as usual. The lining can be renewed at will by blowing matte without silica, and its thickness can be regulated by blowing with more or less silica. Under these conditions the lining should last a very long time, and should be of material value in protecting the magnesite bricks and in prolonging the life of the converter. Greater duty per lining obtained by this practice is ascribed by the authors to the protecting magnetite.

**Zinc Determination at Broken Hill.**—In our last issue, page 54, we gave a synopsis of the method for determining lead as adopted by a sub-committee of the Australasian Institute of Mining Engineers, and published in the *Proceedings* of that society, No. 10, 1913. The method for zinc adopted by the same committee is given herewith.

The committee considered only two methods, viz., titration of the zinc with potassium ferrocyanide, (1) in acid solution, and (2) in alkaline solution. Interfering elements in both processes are cadmium, copper, nickel, cobalt, manganese, iron and aluminium, and these must be separated before titration. Two modifications of the second method are given, consisting respectively in one and two precipitations of iron and manganese.

The titration in acid solution is well known in this country, and is considered standard. Opinions will be found to differ among our chemists as to the value of re-solution and precipitation of the iron and manganese. The Australian chemists, however, have adopted the titration in alkaline solution, with two treatments of the iron-manganese residue.

### *Solutions Required*

*Potassium Ferrocyanide.*—32.5 grams of the pure salt are dissolved in one litre of distilled water.

*Ferric Chloride and Potassium Tartrate Emulsion.*—200 grams cream of tartar and 2 cc. neutral ferric chloride solution containing 10 per cent iron are added to one litre of water. The emulsion must be well shaken before using.

*Outside Indicator.*—Pure glacial acetic acid, 99-100 per cent.

Pure metallic zinc or zinc oxide may be used for standardizing, but the latter should be ignited first to about 600 deg. C. and cooled in a dessicator. In the case of zinc weigh two lots of 0.25 gram and 0.1 gram, or of zinc oxide 0.3 and 0.1 gram, and dissolve in 5 cc. dilute $HNO_3$ (1.4). Evaporate gently until nearly dry and dilute with 100 cc. hot water. Add 7 grams $NH_4Cl$ and 8 cc. ammonia, make up to 300 cc. with hot 1 per cent $NH_4Cl$ solution, add 30 cc. tartrate emulsion, and titrate with ferrocyanide solution until

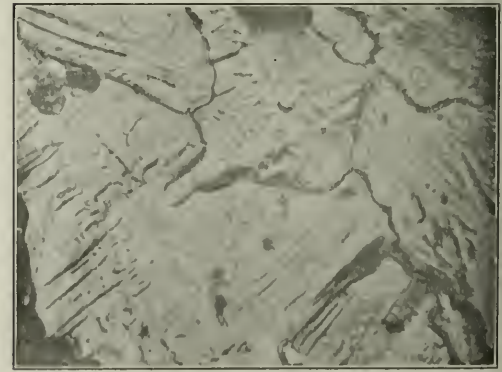

FIG. 4—GOLD (0.5% PLATINUM)

one drop added to a drop of glacial acetic acid gives a faint blue color. The standard and blank are calculated as explained for lead. (See January 1914 issue, p. 54.)

For sulphide ores weigh out 0.5, 1 or 2 grams, depending on the grade of the ore. No titration should require more than 25 cc. of the standard solution. Add 10 cc. $HNO_3$ and warm gently until decomposition is complete. Add 1 gram pulverized potassium chlorate and evaporate to dryness, avoiding overheating. For oxidized ores weigh similar quantities and treat first with 10 cc. HCl and evaporate nearly to dryness. Then add 10 cc. $HNO_3$, boil until all the HCl is decomposed, add the $KClO_3$ and proceed as above.

Treat the dry residue with 100 cc. water, 7 grams $NH_4Cl$, 15cc. $NH_4OH$, about ½ gram sodium peroxide, and boil for about 2 minutes. Allow to settle and then filter, washing two or three times with boiling 1 per cent solution $NH_4Cl$. Re-dissolve the precipitate in HCl, and reprecipitate the iron and manganese with 15 cc. $NH_4OH$ and 2 to 5 grams sodium peroxide. Boil for a few minutes, filter and wash as before. Heat the zinc solution to 70 deg. C., add 30 cc. tartrate emulsion titrate as directed above. If copper is present it is precipitated with granulated lead, the solution decantated and washed from the lead, treated with 30 cc. emulsion and 8 cc. $NH_4OH$ and titrated as before.

With very low grade ores the amount of ammonia may prevent precipitation of the zinc, and in such cases the solution must be treated with acetic acid until a precipitate begins to form, when the titration may be completed. The solution must not become acid.

The use of a small amount of sodium peroxide in the first precipitation is advantageous in two ways—it insures complete precipitation of the manganese and prevents bumping on boiling. The acetic acid used as indicator must be 99-100 per cent strong.

## Recent Chemical and Metallurgical Patents

### Iron and Steel

**Utilizing Blast-Furnace Flue-Dust.**—The incorporation of blast-furnace flue-dust in molten iron flowing from a furnace is suggested in a patent granted to Mr. Ralph Baggaley, of Pittsburgh, Pa. The process is similar to one patented by the same inventor in connection with copper smelting, in which it is proposed to incorporate flue-dust with molten matte before sending the latter to the converter. The inventor claims that his proposed method will be more simple than briquetting or bonding, and will obviate the difficulties encountered in those processes. He uses preferably a bath of molten iron as it comes from the furnace, and mingles with it the dry material to a point short of solidification. The mixture is then cast or taken in molten condition to Bessemer converters, open-hearth or electric furnaces where the refining stage is practiced. In carrying out the process, the heavy molten pig-iron is allowed to fall from four to six feet, or such a distance as will create a suitable vortex in the mixing vessel. The flue-dust is then discharged continuously at a point within the vortex and thus incorporated with the molten mass. It is not recommended that this process be used when the furnace is producing iron intended for remelting in a foundry, but rather when the furnace product is to be refined. (1,081,921, Dec. 16, 1913.)

**Nodulizing Fine Ore.**—In order to prevent the formation of rings of sintered material in nodulizing kilns, Mr. Lewis P. Ross, of Standish, N. Y., has patented a form of rotary kiln with cooling means so arranged that there are sections of low temperature in the walls of the kiln. This results in zones in which no adhesion occurs, between which the adhering material accumulates in separate sections. The latter ultimately fall of their own weight due to the lack of support. (1,081,063, Dec. 9, 1913.)

### Copper and Zinc

**Apparatus for Ammonia Process.**—In Fig. 1 is shown apparatus forming a part of an extraction plant for the recovery of zinc and copper from ores by means of ammonia. It is the invention of Mr. S. E. Bretherton, of Berkeley, Calif., who has been investigating the amenability of certain base ores to this process.

Two agitators A, A′ of like construction are arranged preferably close to each other as shown. From the apexes of the cone bottom pipes C, C′ are connected by branches D, D′ with the discharge pipe E of a pump F, the latter being driven by a motor G. The inlet pipe H of the pump F is connected by branch I with various tanks (not shown) for pumping solutions needed in the process. From the branch pipes D, D′ extend pipes J, J′ which enter the agitators and terminate at the lower end of the agitating tubes K, K′. The pipe H also has connections L, L′ extending into the settling tubes N, N′. Decanters O, O′ are connected by flexible tubes with pipes $O^4$ and $O^5$ which lead to pipe $O^6$ that is connected with a sump for receiving solution decanted from the agitators. Gages P, P′ are arranged on the sides of the agitators to show the height of pulp in each. The closed tops of the agitators are connected with each other by pipe Q for conducting gases back and forth during decantation and filling of the agitators. Means for discharging treated pulp from the agitators is provided in the pipes R, R′ leading to $R^4$. The discharged pulp may be conducted to filter press or leaching tanks for the extraction of contained gold and silver.

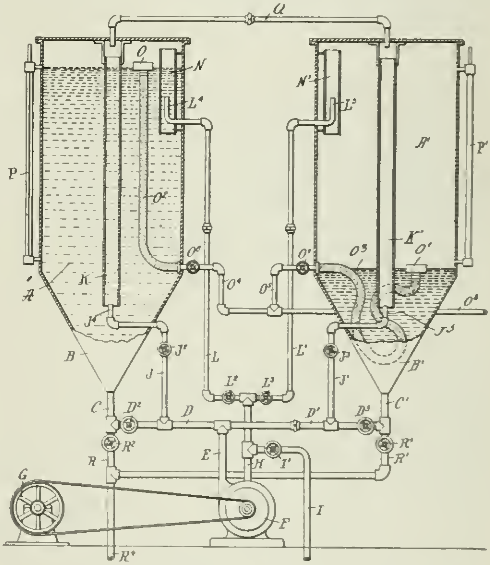

FIG. 1—AGITATORS FOR TREATMENT OF ORE BY AMMONIA PROCESS

The cycle of operations is as follows: 1. filling A (decanting wash A′); 2. agitating A (removing residue A′); 3. decanting A (filling A′); 4. rest (agitating A′); 5, filling wash A (decanting A′); 6. agitating wash A (rest); 7. decanting wash A (filling wash A′); 8, removing residue A (agitating wash A′). It is to be understood, of course, that the necessary valves are operated in connection with these operations. Agitation consists in circulating the contents of an agitator. The decanted solution is run to suitable precipitating apparatus. In the operation described it will be seen that decantation is effected without the admission of atmospheric air, since the gas contained in either agitator may flow into the other during decantation, and back again during filling with a new charge. Thus the dilution of the gas is prevented and impairment of the decanting process avoided. (1,082,797, Dec. 30, 1913.)

**Collecting Zinc Oxide Fume.**—As a substitute for canvas bags in the collection of zinc oxide, Mr. Morley P. Reynolds, of Cleveland, O., has patented a special form of apparatus with mechanical means for scraping the oxide from the collecting medium. The collector comprises two vertical cylindrical bags of wire cloth, supported concentrically, with an appreciable space between them. The wire fabric is strengthened and supported by T-bars attached exteriorly and running vertically. Suitable sheet metal covers close the tops of the bags. A vertical shaft extends centrally through the bags and is connected with a source of power at its upper end outside the bags, and journaled in a steadying bar below the bags. Attached to the shaft are arms carrying vertical wire brushes that may be caused to revolve against the inner surfaces of the bags and dislodge any material attached thereto. In operation the zinc oxide fume is introduced into the apparatus through a pipe at the bottom. Most of the oxide is caught on the inner bag, and such fume as passes the first bag is caught on the second. When sufficient fume has been collected, the wire brushes are put in motion to scrape the oxide from the bags and allow it to fall into a collecting receptacle which closes the bottom of the apparatus. The inventor claims that the device will be more effective than canvas bags, more convenient and less expensive. (1,082,766, Dec. 30, 1913.)

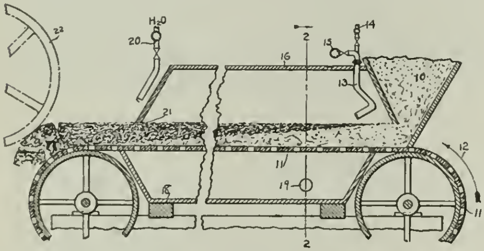

FIG. 2—HALL PROCESS FOR ELIMINATING SULPHUR FROM ORES

**The chloridizing roasting of ores**, such as copper, from which most of the sulphur content has been eliminated, has been carried out in various ways. Thus, after the ore has been heated to the proper temperature, salt has been added in the last stages of roasting and incorporated by rabbling. According to a patented improvement of Mr. Augustus D. Ledoux, of Summit, N. J., chloridizing can be carried on as a continuous process, dispensing with extraneous heat with the exception of such as may be needed to start chemical reaction between the ore and salt. Thereafter the process continues due to the heat generated by the chemical reaction. The operation can be carried on in a furnace of the MacDougal type. The applied heat of combustion starts chemical reaction which increases as the charge progresses through the furnace, and the process becomes continuous without further aid of heat from any extraneous source. (1,082,599, Dec. 30, 1913.)

**Hall Process of Desulphurizing Ores.**—The recovery of elemental sulphur from sulphide ores by roasting in a reducing atmosphere with admission of steam, is a process that is of interest to the copper smelter. In a patent recently issued to Mr. William A. Hall, of New York, N. Y., the inventor shows the application of his process in connection with a down-draft sintering furnace of the Dwight & Lloyd type. Fig. 2 shows such a furnace with an endless traveling grate on which an ore mixture is fed from a hopper. A combustion chamber 16 covers part of the grate surface where the reaction takes place. Immediately beneath the combustion chamber is another hood 18 provided with an outlet 19 leading to a suitable suction. Within the combustion chamber is a burner 13 adapted to use liquid or gaseous fuel. The flame is always maintained in a reducing condition. Steam is added through the pipe 15. A small stream of water may be applied to the ore as it leaves the combustion zone. The operation results in the elimination of sulphur in the elemental state, and its subsequent recovery in a suitable washer. At the same time the ore is sintered according to the process of Dwight & Lloyd. (1,083,252, Dec. 30, 1913.)

### Laboratory Apparatus

**Refractory porous articles**, such as filtering tubes, diaphragms, etc., in various shapes and for different purposes may be produced according to the specifications of a patent recently issued to Mr. Percy A. Boeck, of Worcester, Mass., and assigned by him to the Norton Company of the same place. Bauxite or other impure form of alumina, or purified alumina prepared by chemical methods, is fused in an electric furnace. This product is then crushed, forming what the inventor terms "alumina grain." The grain is then roasted to remove any trace of carbides or similar products, and mixed with a small proportion, 5 to 15 per cent, of plastic clay and sufficient water to form a thin slip. The desired article is then molded from this slip, dried at about 50 deg. C., and fired in a kiln at a temperature sufficiently high to vitrify or partly vitrify the bond. The resulting article is porous and retains in large degree the chemical inertness and refractory character of the alumina grain. (1,081,573, Dec. 16, 1913.)

**Glazed refractory articles** of the above nature, such as crucibles, combustion boats, insulators, etc., are made as described above, and then treated with a glaze compound which is the invention of Mr. Arthur T. Malm, of Worcester, Mass. Since the refractory alumina article described above has a high coefficient of expansion at temperatures below white heat, it is necessary to use a glaze of approximately the same coefficient of expansion. A porcelainic glaze of the following composition has been found satisfactory.

| | |
|---|---|
| Feldspar | 41.8% |
| Flint | 27.3 |
| Whiting ($CaCO_3$) | 17.7 |
| Clay | 13.2 |

A lead glaze compounded as follows also has proved suitable.

| | |
|---|---|
| Feldspar | 26.37 |
| Whiting ($CaCO_3$) | 14.38 |
| White Lead | 12.37 |
| Clay | 12.37 |
| Flint | 34.51 |

Crucibles and other articles of laboratory use prepared in this manner are said to be more serviceable and durable than glazed porcelain which they resemble in appearance. The thermal conductivity is greater than that of porcelain, which permits of quicker and more economical heating and reduces the strain in the walls during heating and cooling. (1,081,542, Dec. 16, 1913.)

## The Parral Tank System in the Leaching of Copper Ores

In view of the wide interest attached at present to the treatment of copper ores by leaching with acids, the application of the Parral agitating tank for this purpose, is of particular interest.

The Parral tank was first used in Mexico in cyanide practice as fully described in our Vol. X, pp. 48 and 434, replacing the Pachuca tank. If we compare the Parral and Pachuca tanks the objectionable height of the Pachuca tank is avoided in the low form of the Parral. In the Pachuca tank a definite ratio of height to diameter must be preserved, while in the Parral no cognizance of this ratio need be taken.

In the Parral tank system the agitation is effected by a plurality of transfer pipes of comparatively small diameter through which the continuous transfer of the pulp from the bottom to the top of the tank is brought about by compressed air. Compressed air is admitted to the bottom of these transfer pipes through a nozzle fitted with a ball valve which automatically opens and closes as required in the jet feeding of compressed air. The discharge ends of the transfer pipes are horizontal and so directed that the discharging pulp will spout in the same direction with respect to the interior side of the tank and in line with segment cords thereto. This method of discharge sets up a rotary current in the tank charge which flows round and round within the tank and keeps the whole charge in rotary motion from top to bottom of tank.

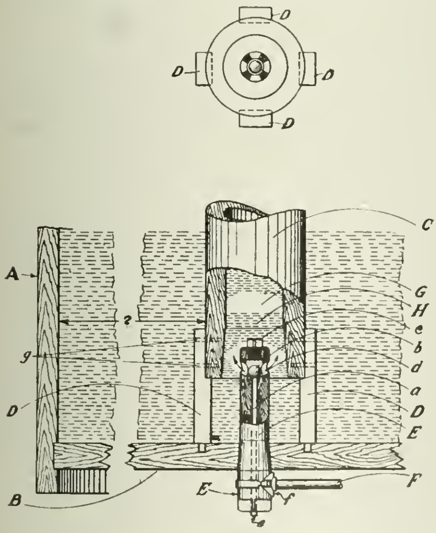

FIG. 1—AIR NOZZLE AND AGITATION PIPE FOR ACID SOLUTION

If the Parral tank is to be used in copper metallurgy for the treatment of slimes and flue dust in acid solutions, the tank, the transfer-pipes, and the air-nozzle are made entirely of wood and the ball in the air-nozzle is made of glass so that all the material used is acid-proof. Fig. 1 illustrates the arrangement for acid leaching, showing a corner of the tank, one transfer-pipe, the wooden air-nozzle with the compressed air pipe attached thereto and the glass ball seated on the compressed-air axifice to prevent the entrance of the said solution when the air is off.

*A* are the staves of the tank side, *B* the bottom of the tank, *C* the transfer-pipe, *D* the wooden legs supporting the transfer-pipe, *E* the compressed air-nozzle inserted up through the bottom of the tank, *F* the wrought iron compressed-air pipe attached to the wooden nozzle by a strap flange, *G* the compressed-air disc in the transfer pipe, *H* the alternating pulp sections carried upwards between the air-discs.

The air hole bored through the nozzle is shown at *a*, while *b* is the glass ball which closes the air nozzle and prevents the entrance of the acid solution; *c* is the top screw plug which closes the top of the air nozzle after the ball is dropped in; the four vents through which the compressed air enters the transfer pipe are shown at *d*.

This apparatus can be cheaply installed in any wooden tank and, as the illustration shows, the removal and replacement of an air nozzle may be quickly and easily effected.

With this equipment the settlement of the pulp after agitation, the decantation of the pregnant solution, a second dilution of the pulp with weak solution followed by reagitation, a second settlement and decantation followed by final water-wash of the pulp may be carried on in the same tank when properly equipped for the purpose, or it may be carried on in stages in different tanks if so desired.

The patents of the Parral tank system are owned by Mr. Bernard MacDonald, 1005 Fair Oaks Avenue, South Pasadena, California.

## Personal

Mr. **T. F. Baily**, president of the Electric Furnace Company of America, of Alliance, Ohio, delivered recently before the Pittsburgh Foundrymen's Association on his "electric furnace for reheating and annealing as applied to steel foundry practice."

Mr. **J. M. Callow**, of the General Engineering Co., Salt Lake City, Utah, is in charge of the construction of the new concentrator for the Magna Copper Co., Superior, Ariz.

Mr. **Angus Cameron**, president of the Radium Company of America, Sellersville, Pa., is traveling in the West and will visit the mining sections in Colorado and Utah, where his company have interests and stations, and will personally deliver parcels of radium. The policy of this company is to furnish their radium to medical practitioners in the United States.

Mr. **J. E. Clennell** is on the technical staff of Charles Butters, and is in charge of the new testing laboratories lately established in San Francisco.

Mr. **William M. Corse**, the well known secretary of the American Institute of Metals, has severed his connection with the Lumen Bearing Co. to associate himself with the Empire Smelting Co., of Depew, N. Y., in the capacity of general manager.

Mr. **Louis Emanuel** is superintendent of the smelter of the Arizona Consolidated Copper Co., at Humboldt, Ariz.

Mr. **O. A. EnHolm** has severed his connection with the Electric Heating Apparatus Co., and is devoting his time to his own personal matters and experimental work.

Mr. **Ernest P. Humbert**, of Niagara Falls, N. Y., formerly assistant of Dr. Paul Héroult, delivered recently before the Pittsburgh Foundrymen's Association an address on "the electric steel refining furnace in the foundry."

Mr. **O. C. Schaefer** has been selected as operating superintendent of the mill of the National Radium Institute, now being built in Denver.

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

### REFINING METALS (*Continued*).

625,864, May 30, 1899, Emil Wohlwill, of Hamburg, Germany.

Relates to the electrodeposition of gold, and refers to his prior application which became patent 625,863. The present patent differs from that in that a part or all of the hydrochloric acid is substituted by a soluble chloride capable of forming a double salt with the gold, such as sodium chloride. The electrolysis is preferably carried at 60° to 70° C.; the quantity of chloride added is increased with lower temperatures, or with increased current density. In view of the solubility of silver chloride in sodium chloride, the latter should not exceed 100 grams per liter. In the presence of platinum and iridium, potassium chloride or ammonium chloride should not be used.

636,321, Nov. 7, 1899, Thomas Craney, of Bay City, Michigan.

Relates to the extraction and deposition of copper from large masses or boulders of native copper, such as are found in the Lake Superior District. Such masses of copper sometimes weigh from twenty-five to one hundred and fifty tons, and owing to their shape cannot be profitably mined. A suitable cavity is made in such a mass and filled with an electrolyte such as acidulated copper sulphate, the mass of copper is connected as anode, and a cathode inserted in the electrolyte. During the electrolysis, the cavity is occasionally cleaned to remove any slimes which may contain gold or silver, a fresh cathode inserted, and the operation continued.

657,119, September 4, 1900, Frank Klepetko and John T. Morrow, of Great Falls, Mont.

Relates to the deposition of copper. States that if to a solution of copper sulphate containing twelve parts by weight of sulphuric acid, fourteen parts by weight of copper sulphate, and seventy-four parts of water, about one or two per cent by weight of wood-tea is added, the deposited copper is smoother, denser, and purer; its character being materially changed and improved. The wood-tea further serves to lessen the influence of the antimony, in that the latter may be allowed to accumulate to a much larger extent without contamination of the deposited copper. The wood-tea may be prepared by soaking wood in water highly heated by steam.

669,439, March 5, 1901, Hans A. Frasch, of Hamilton, Canada.

Relates to apparatus for carrying out the process described in his copending application which became patent 669,440. The apparatus consists of a tank with a brick-lined bottom, in which are tile gratings through which the electrolyte enters. Passing through a side of the tank are a plurality of anodes of carbon, located between the tile gratings. Upon the bottom, and covering the anodes, is placed the suitably ground matte or ore containing the metal to be extracted. Above the matte is placed a layer of sand as a diaphragm. The cathodes project into the space above the sand. The electrolyte is drawn off from the upper part of the cell and circulated through the matte and in contact with the anodes.

669,440, March 5, 1901, Hans A. Frasch, of Hamilton, Canada.

Relates to extracting such metals as copper, nickel, cobalt, etc., whose hydroxids are soluble in ammonia, from their matte, ores, etc., containing them. The matte or ore is suitably ground and spread over the bottom of a tank in contact with carbon anodes. Through the mass of matte, etc., is percolated a solution of a salt of ammonium, such as ammonium sulphate; this solution is decomposed by the electric current, the anions combining with the metal to be extracted in the matte, and forming a double salt with the excess of ammonium salt. Above the layer of matte is a diaphragm of sand, etc. Above this is a large volume of electrolyte from which the metal is deposited upon suitable cathodes. The ammonium salt electrolyte is then withdrawn and supplied to the lower layer of matte, etc. The patent contains a reference to his copending application for the apparatus which became patent 669,439.

## Book Review

**De Re Metallica.** By **Georgius Agricola.** Translated from the First Latin Edition of 1556, by **Herbert Clark Hoover** and **Lou Henry Hoover.** Quarto (20 x 33 cm.), 637 pages, numerous illustrations from the original. Price in America $8, in England 25 shillings. London: The Mining Magazine. San Francisco & New York: The Mining & Scientific Press.

At the annual meeting of the Mining and Metallurgical Society of America, in New York City, January 13, the annual medal of the society was awarded to Mr. and Mrs. Hoover, in recognition of this great contribution to English metallurgical literature. This is timely and well-deserved recognition of a great literary task splendidly completed.

Heretofore this patriarch of books on mining and metallurgy has been practically inaccessible to the English technologist. We do not wish it inferred that the mining engineer or metallurgist has been thus deprived of a great technical vade mecum, but he has been cut off from a clear and highly interesting account of the beginning of modern mining and metallurgy. Just as a great picture must be viewed from one certain standpoint in order to see all its parts in their proper proportion and perspective, so the literature of mining and metallurgy focuses to the vanishing point in the book of Agricola, and needs to be viewed from this starting point in order to be seen in proper perspective. The possession of this translation completes the literature of mining and metallurgy, in English, at the beginning; the other end is perpetually being finished, up to date, but will never be completed.

To every one who knows and loves mining and metallurgy, we say "get this book, and love it more." It is like getting personally acquainted with one's ancestors. Relatively in the dark regarding the correct principles of mechanics, physics and chemistry, yet these old practitioners teach us many lessons of patience, perseverance, common sense and skillful adaptation of means to ends. Inferior to us only in the knowledge (most of which is not to our personal credit), they were certainly our equals and often our superiors in applying what they did know to useful ends. The essentially human achievements of these old practitioners give us a fraternal feeling across the three and a half centuries which makes us proud to call ourselves their successors.

The explanatory technical notes added by the translators are simply admirable.

We wish to add our congratulations to those which are coming from all sides to the distinguished translators. Their achievement may properly be included in Fabricius's eulogy of Agricola's work: "Death comes to all, but great achievements raise a monument which shall endure until the sun grows cold."

## The Laws of Crushing

Will someone with a mathematical mind and a practical knowledge of the art of crushing rock, volunteer to sacrifice himself in the interests of science by attempting a satisfactory solution of the vexed question as to whether the laws of Rittinger or Kick apply in the work of crushing? Is the work of crushing proportional, respectively, to the reduction in diameter of the particles, or does it vary as the volumes and weights of these bodies?

There are staunch advocates of both of these contentions. Stadler, of South Africa, is firm in the support of Kick's law; and recent investigators at McGill University in Canada are said to have arrived at similar conclusions. More recently Taggart, of Yale, has taken the same stand. On the other side, Del Mar and Gates and Robert H. Richards have publicly supported the law of Rittinger, which Stadler says is a myth resulting from a misinterpretation of Rittinger's words.

This leaves us in suspense. From Rittinger and Kick on down to the latest convert, the various advocates have commanded respect for their knowledge and ability. And yet on this point they are in disagreement and have divided an otherwise united following into two camps. The way is open for someone to harmonize the two factions. In the meantime the mechanical efficiencies of crushing machines and the power consumed in the work of crushing will remain moot questions until agreement is reached as to the proper method of calculation.

## The Statistics of Pig Iron Production

Of the 30,966,301 gross tons of pig iron produced in the United States in 1913, 16,738,952 tons, or 54 per cent., was delivered in molten condition, according to the official statistics issued the middle of February. The quantity of iron other than Bessemer and basic disposed of in molten condition is negligible, while the tonnage of Bessemer and basic produced amounted to 23,814,313 tons, of which the molten iron reported is 70.3 per cent. This indicates a very large employment indeed of direct furnace metal, since owing to the exigencies of Sundays and holidays, as well as blast furnaces running ahead of their attendant steel plants, it is necessary to cast considerable pig iron at plants which regularly use direct metal. It is probably safe to conclude that between 80 and 85 per cent. of the total steel production of the country is made at plants which regularly use the direct metal process, the remaining steel being made at detached steel works which use cold pig, usually purchased in the open market.

The segregation of pig iron into the forms in which cast or delivered commenced only with the year 1912, so that comparative statistics are lacking to show the growth of the direct metal process, but it is well known that it was not used in plants which produced as much as half the total steel production. The statistics returned are as follows, "chill cast" meaning simply iron which was cast in loose chills, set by hand, instead of in chills carried mechanically:

| | 1912 | 1913 |
|---|---|---|
| Molten condition | 16,466,722 | 16,738,952 |
| Sand cast | 6,309,495 | 6,689,680 |
| Machine cast | 6,214,121 | 6,522,075 |
| Chill cast | 6,726,017 | 1,000,172 |
| Direct castings | 10,582 | 15,422 |
| Total | 29,726,937 | 30,966,301 |

An improvement is introduced in the 1913 statistics, by the segregation of merchant pig iron. The tonnage made for sale is given at 9,734,238 tons, the quantity made for the use of the producers being 21,232,063 tons. The latter item is made up almost exclusively of pig iron made by the regular steel interests, and includes almost all of the 16,738,952 tons reported as delivered molten.

The production of pig iron in 1913 established a new record, passing the 1912 output by 1,239,364 tons, or 4.2 per cent. The year 1906 stands out as the last year during which there was full production throughout the year, the 25,307,191 tons produced in that year representing substantially the full capacity of the furnaces in existence. In 1913 there was not full employment of the existing furnaces, yet there was a gain over 1906 of between 22 and 23 per cent. in the tonnage output. This, however, was quite a moderate gain for pig iron in seven years, seeing that in the past production has usually doubled about once in ten years. However, the 1913 production was nearly double that of 1901, and as much more than double the output in any year previous to 1901. The present capacity may be taken as between 34,000,000 and 35,000,000 tons, or 3,000,000 to 4,000,000 tons in excess of the actual output last year. This estimate of capacity is based upon the possibilities of actual commercial performance, with raw materials and finished products selling at moderate, but not ordinarily profitless prices. The physical capacity, including furnaces which can operate profitably only when there is a very wide margin, is perhaps several million tons greater.

## Improvements in Copper Converting

Basic-lined copper converters have practically superseded those with acid lining, with attendant great increase in the duty per lining. Practice has changed radically, from providing a lining which was intended to be consumed, to one presumed to be chemically inert under the conditions existing in the converting process. The present tendency is to make every effort to protect the lining from destruction and to supply from without the necessary fluxing ingredients to convert the matte to blister copper.

In this connection the recently patented idea of Messrs. A. E. Wheeler and M. W. Krejci, of Great Falls, Mont., bids fair to have a wide influence on the metallurgy of copper. They coat the basic lining of a converter with a layer of magnetite so that no portion of the lining is exposed, and is thus protected from destruction. This protective layer is formed synthetically when the converter is first placed in commission and its thickness is thereafter controlled by attention to details of operation. The principle involved is that the blowing of matte with a deficiency of silica results in the formation of magnetite.

When a converter is operated in accordance with the idea of Wheeler and Krejci, its basic lining receives a monolithic coating that prevents mechanical or chemical disintegration, unless improper converting temperatures are employed. The magnetite coating has a melting point some 300° C. higher than the temperature at which converting takes place, which is a good margin in favor of the maintenance of the coating. And since the deposition of magnetite can be controlled by regulating the proportion of silica supplied to the matte, a converter once lined and coated should, in theory, never require relining. Practically the effect is to greatly prolong the life of the converter and to reduce converting costs by securing greater duty per lining.

Basic linings of magnesite brick in copper converters have been in use only a few years, but during that time they have abundantly proved their superiority. Steady improvement in the process of basic converting has followed the successive adoption of the method at Baltimore, Garfield, Anaconda and Great Falls. Basic linings protected as above described have lasted over two years, which is in marked contrast to former practice, either acid or basic. The patent claims on the process are broad, not being restricted to the deposition of magnetite on basic linings, but generally to the process of forming monolithic furnace linings by the oxidation of base-metal components of the converter charge.

## How the World Pays for Engineering Progress

The subject of the cost and price of any commodity is one of the most difficult in the science of economics. In practical affairs, between buyer and seller, it is likewise a hard proposition. But it is logical to conclude that the cost of production is the integrated amount of human effort measured in terms of "mendays"—for the work of the unskilled laborer for one day is a proper and sound unit for such a purpose—which is given by the world in the production of the commodity under question. To measure this amount is quite another question. We suppose it is natural to assume that the average price less a certain profit apportions this accurately. In the final analysis, there exists a certain charge more or less incommensurate but still actual. This charge is the price the industry pays for the immense amount of unproductive experimenting.

The fact that the community pays for the failures of any enterprise is shown by the remark so often made that it costs more to mine gold than the gold is worth and that the losses of the failures are not paid for by the profits of the successes. We believe that this is not strictly true but that there is an element of truth in it, and that it is widely true that the high profits derived from successful attempts to gain mineral wealth include insurance against failure. Mining engineers who lay the proper stress on the commercial side of mining insist that mining stocks should return from 10 to 20 per cent on the market value to allow for the exhaustion of mineral and to recompense the investor for previous losses. This is only right.

It is plain that the same conditions hold in the case of a reduction works that treats a crude mineral and produces a commodity useful to the community. There is always change, for the only thing unchangeable is human mutability. After countless failures a successful new process brings it about that the old plants must be "scrapped." So we see that in the constant flux of metallurgy there is always progress and that new processes when "practicalized," thereby render the old plants obsolete and make mines of deposits whose ores were commercially unavoidable. This, of course, has the effect of annihilating or at least depreciating the value of existing plants.

In any proper system of accounting there should be a charge to cover this loss. In electrical engineering where progress is rapid and sure this is set down under the item of "depreciation due to the advance in the state of the art." We have pointed out that in metallurgical engineering the changes proceed slower and with less apparent certainty than in electrical engineering, due to the fact that "commercial inertia" is greater in the former art than in the latter.

But in the metal business, progress though seemingly slow and made by saltations, is none the less an inexorable condition of existence. It is, moreover, costly and the world pays the reckoning in the price it pays for iron, copper, lead, zinc, and the other metals.

It is well known that pioneers in the introduction of any new process struggle along now intelligently, now aimlessly, and only attain progress by perseverance. We have the word of Sir Roberts-Austen that Sir Henry Bessemer made seventeen different types of steel converters before he hit upon a satisfactory and practical form of apparatus. Then, too, it was much improved by Holly and others in America.

It seems to be indubitable in view of the great amount of time, human energy, and money expended in the endeavors to "practicalize" new processes, that in any broad analysis of metal prices and metal costs, the consumer finally pays for all of it. For instance, take the case of improvements in the metallurgy of complex zinc-lead sulphides. A low estimate of the cost of attempts to develop the alluring hydrometallurgical processes, whose name is legion in association with that of zinc, is $15,000,000. In one sense this is all wasted. But in no other way does the world learn what can be done and what cannot be done, and if a successful process of any kind be developed, the returns to the world will be vastly greater than $15,000,000.

We see in the evolution of the fauna and of the flora that nature shows an equal and similar ruthlessness. She progresses slowing, evolving out of her wayward children the "sports," which are variations from the normal of existing species, a new type that is fitted to the new environment. But hardly one out of the myriad of "sports" is the successful variant that is the ancestor of the type of the future. There is, or rather there seems to be, a vast amount of unintelligence in the means by which nature progresses.

To have seen clearly in this apparent unintelligence, an ever-present intelligence that guides the force of nature, this must be placed to the credit of Henri Bergson and explains his immense present popularity among philosophizing humanity. This French Jew has superinduced upon the naturalistic philosophy of Herbert Spencer a lofty and noble spiritualistic superstruction. He typifies in his clear-cut idealistic thought, harmonizing so accurately the emotions and reason, the genius of his race and the genius of his country. He shows in his "Evolution Creatrice" that nature is really the embodiment of intelligence and that evolution is broadly constructive rather than narrowly destructive. His argument is at once sound and as brilliant as are his conclusions inevitable.

On the analogy of his philosophy we see a similar process going on in metallurgy. The useless experiments are unintelligent in one light and intelligent in another light. The sum total of all is progress and progress is the result of the victory of intelligence over inanimate obstacles. Continuing the line of Bergson's thought, it is reasonable to expect that the increased diffusion of applied science will tend to make the cost of progress less and to decrease the bill that civilization charges its inhabitants for metals, the sinews of its warring existence.

---

## The Proof of Puddings and Processes

An old proverb gives a concise and positive rule for determining the value of a certain product of the culinary art, advising us that only in the eating of a pudding are we to find absolute proof of its worth.

In view of the many new chemical and metallurgical processes constantly seeking public favor, it seems proper to paraphrase the above proverb and say that the proof of a process is in the bookkeeping. Good metallurgy lies in making money out of ores, and processes which do that successfully have value. It matters not how ingenious a process may be, nor is it always of consequence that the chemistry and mechanics involved are correct; if the net result is not going to yield more dollars than are spent, the process has no commercial value.

One difficulty in arriving at the value of inoperative processes is that actual figures are not available to show the costs of the various steps. And unless an engineer has data gleaned from similar steps in other allied industries he cannot arrive at a safe approximation of profit and loss. If the proposal is wholly novel its cost may be roughly estimated, but in some cases nothing but an actual test, carefully checked by weights and assays, will reveal the truth. The intrinsic meaning conveyed by the old proverb is a good guide in valuing processes.

## Concentration of Carnotite and the Work of the Bureau of Mines

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—In your issue of February, 1914, I note an extract from Bulletin 70, Bureau of Mines, on the "Concentration of Carnotite by Wet and Dry Methods." According to both the government bulletin and the extract in your journal, it would seem as if the work on concentration of carnotite ores was made public for the first time in the preliminary report by Dr. Moore and Dr. Kithil. This, however, is incorrect.

Up to within the year 1912, it was considered a practical impossibility to concentrate said ore, due to its very fine physical structure. In a report printed by the Colorado Bureau of Mines, 1905, you will find this statement substantiated by Messrs. Fleck and Haldane of the Colorado School of Mines. After some personal research during 1911 and part of 1912, I was convinced that the wet concentration of carnotite ores was a commercial possibility. The results of my investigations, giving data, describing process, and showing the advantages gained by such an operation was published in Metallurgical and Chemical Engineering, in June, 1912, fully one and one-half years previous to the Bureau of Mines' Bulletin 70.

## The Induction Furnace—Its Efficiency and Refining Capabilities

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—In your February, 1914, issue Mr. I. Rennerfelt has brought up a few questions which it might be worth while to discuss a little further as there seems to exist quite some confusion regarding same. I mean the efficiency of various types of electric furnaces and the possibility of refining in induction furnaces. In the following I will confine myself to induction furnaces as I am more familiar with these than with "arc resistance" and "arc radiation" furnaces.

As regards the variance of information regarding the first point it is probably explained by saying that usually not all the factors are taken into consideration in calculating efficiencies and that various statements regarding "efficiency" are not directly comparable as they are based on different assumptions.

When a certain efficiency is stated, the conditions of operation as well as size of furnace, etc., should also be stated.

In the following I will first give an example showing that the efficiency of a furnace will be different under different conditions of service. The figures used are not quoted from furnaces in operation, but merely assumed to illustrate this fact.

Assume that a 20-ton induction furnace is used for melting cold scrap and that the theoretical power consumption per ton of steel which, of course, is the same under all circumstances, is 460 kw-hr. per metric ton; further, that the radiation loss of such a furnace is 7500 kw-hr. per twenty-four hours, and the electrical loss 3 per cent.

Assume also that in Case "A" 70 tons are melted per day, and in Case "B" 50 tons per day.

| | *A* K.W.H. | *B* K.W.H. |
|---|---|---|
| Theoretical power consumption per day, about | 32,000 | 23,000 |
| Radiation loss per 24 hrs., about | 7,500 | 7,500 |
| Electrical loss at 3 per cent, about | 1,200 | 940 |
| Total | 40,700 | 31,440 |
| K.W.H. per ton | 580 | 630 |
| Efficiency | $\frac{32,000}{40,700} = 79\%$ | $\frac{23,000}{31,440} = 73\%$ |

As will be seen, the efficiency in the first case is 79 per cent, in the second case it is 73 per cent. I wish to point out that when a certain efficiency is stated, it must always be explained what is meant by it.

If, on the other hand, someone makes similar calculations as above, but instead of regarding the efficiency as has been done here, he means by these terms the ratio between the power consumption per ton of steel figured out and the actual amount arrived at in practice, which might be somewhat higher on account of inaccuracies in the figures assumed, say 15 per cent higher, he will then state that the efficiency is 85 per cent in both cases.

Regarding the other point, the possibility of refining steel from phosphorus and sulphur and deoxidizing it in induction furnaces, I agree with Mr. Rennerfelt that the engineer who is not an electrometallurgist might be bewildered by the different statements made in this respect. As far as I am personally concerned, I am perfectly satisfied with the knowledge that there is no difficulty at all to refine in induction furnaces, and I wish to make a few remarks which might explain a number of things.

When Kjellin for the first time made steel commercially in an induction furnace in Gysinge, he made use of a furnace consisting merely of a circular channel containing the steel wherein the heat was generated. This channel was covered with lids. Now in order to refine steel for the removal of phosphorus and sulphur the following operations have to be performed:

The steel is first to be covered with an oxidizing slag which absorbs the phosphorus; this slag has to be removed and a new basic slag added to absorb the sulphur. In order to remove the first dephosphorizing slag from the steel in the Kjellin furnace the lids had to be removed and the slag lifted up. When the lids were removed a very large amount of heat escaped, the slag cooled off, and, of course, it was very difficult and time-wasting to remove the slag by lifting it up. It was hardly possible to remove it all. Consequently it was hardly possible to remove the phosphorus since during the following deoxidizing and desulphurizing operations the phosphorus absorbed in the slag, remaining in the furnace, was again reduced and entered the steel again.

The information was, therefore, spread broadcast that the induction furnace could not be used for refining, and also that the slag was not sufficiently fluid. This was true in regard to the first Kjellin furnace whereas in the Roechling-Rodenhauser furnace and the improved type of double-ring Frick furnace there is no difficulty at all in refining the steel or keeping the slag fluid, especially when they are made tilting, and with lateral doors, which latter arrangement goes a long way toward decreasing radiation losses.

As regards the statements made several times that the slag must be like a watery liquid and overheated to a high degree in order to be able to absorb sulphur and hotter than the steel, I think these are exaggerating statements. The only condition necessary, with the exception, of course, of conditions as to composition of slag, etc., is to have the temperature at the surface between the steel and the slag, which is the place where the reactions take place, sufficiently high. Even assuming that it should be necessary to keep the slag in a watery condition, this can be done in an induction furnace by merely increasing the temperature in the furnace. Of course, the steel will also get hotter, and it has been said that it will be overheated. What is the meaning of this? The steel covered by a protecting layer of deoxidized quiet slag which, at no point allows possible air or oxidizing gases present to attack it, cannot possibly be injured by a very high temperature derived from the heat which is generated in the steel itself.

William Björkstedt.

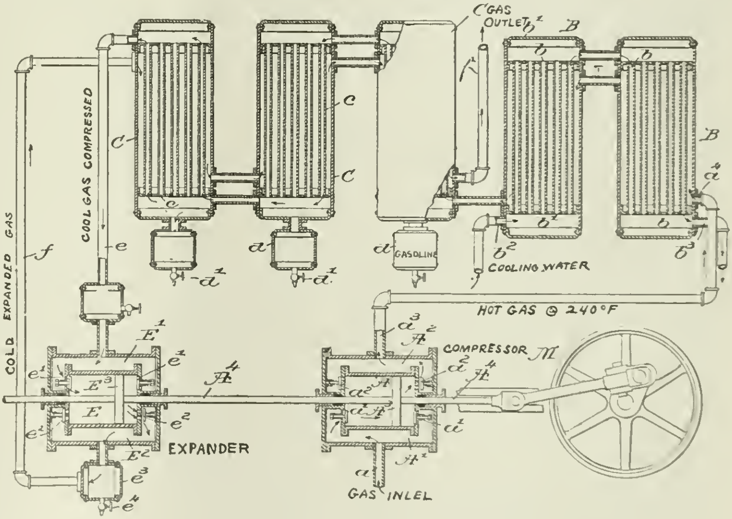
## The Patent Processes for Making Casing Head Gasoline

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Within the last few years the industry of producing gasoline and light boiling fluids from casing head gas and some natural and artificial gas has become a large industry and many patents on the subject have appeared and many patented processes are being developed. In some cases the patents have only been applied for and in others patents have been granted.

Under our patent system each application is examined to ascertain whether the applicant has any invention and no matter how small a part of a process an invention is, a patent may be obtained on this new feature. This novelty may be actually useful or necessary to success or it may be only asserted to be useful by the applicant. No question is usually raised as to usefulness of a patent by the patent office, as it is left for future development to show that. One may also secure a patent and yet not be able to use it on account of the prior patents dominating him. Also the patent office examination is not accepted by the courts as complete or really having much weight and when the patent is litigated in the courts a prior patent may be held to render the later one invalid.



DRAWING OF HEINZERLING APPARATUS

On this account a prospective investor in patents must know something of the previous patents and what is known as "the state of the art."

A brief review of the art and patents should therefore be of timely interest.

Of course, it has always been known that there were so-called "wet gases," particularly among the "casing head" gases or those coming from a well in which oil was also produced. It was known that the gas contained oil and that the oil contained gas. The patent to Grieg and Smith, No. 42,121, of 1864, states that "Petroleum on being taken from the wells contains a large quantity of gas which when separated from the oil can be used for fuel."

This patent only discloses a method of ridding the oil from gas by blowing air through it.

In 1866 Johnson received patent No. 54,917, which clearly discloses the art of "rendering liquid the vapors which rise with or are forced up with petroleum." These are "light benzine, naphtha, etc."

The specification discloses the compression of the vapors by means of "lift or force pump" . . . "connected to a suitable condenser from which I gather the condensed liquid products into barrels," etc.

He states: "I employ power to actuate the pump."

His claims include "a new article of commerce, viz., the light condensable vapors which rise with petroleum and which may be pumped off under any suitable seal and condensed."

Here is clearly disclosed the primary operations of compressing casinghead gas and condensing out "the light benzine, naphtha, etc."

Consequently there can be no patents in existence which dominate the two primary operations necessary to produce casinghead gasoline.

In carrying on any commercial operation, economy is, of course, necessary and apparatus working in an economical way is, of course, an essential, but in the Heinzerling patent of 1897, No. 575,714, which expired Jan. 28, 1914, there is shown an air compressor or gas compressor cylinder and a gas expansion cylinder, both coupled to a flywheel with a series of condensers and heat exchangers between. The specification clearly explains that the gas is to be compressed in the first cylinder and cooled in two condensers in series; with condensation of the condensable liquids, which are removed by appropriate valved containers depending from and connected with the condensers. Thence the water-cooled gas passes to other condensers cooled by the residual gas which is meantime expanded in the second cylinder, which thus aids the compression. The expansion produces cold gas which afterwards, circulating through the last condensers, cools the compressed gas to a point stated to be between —25 and —40 deg. C. The first water cooling refrigerates the gas, as stated, to 10 deg. C.

Furthermore, this patent discloses the cooling of the gases by direct contact with cooling liquids such as calcium chloride and glycerine.

It states that "petroleum, benzine" and some others are not soluble in glycerine. The patent states "this method of direct cooling by liquids is limited, as the substance to be separated must be insoluble in the liquid."

While this patent is not specifically directed to the production of casinghead gasoline, as the applicant was a German who probably never knew anything about this gas, yet the patent covers broadly any gases containing a volatile liquid, and the same machinery and process can be used on any gas, and no subsequent patent can claim any special gas unless it is shown that the special gas acts differently than any described in the patent.

It would appear, therefore, that the field is open to anyone to produce casinghead gasoline by using compression and condensation broadly or to use compression and water cooling on a gas and to subsequently expand the gas in a steam cylinder to help the compressor along, and that while compressing, the gas may be cooled with water, calcium chloride or glycerine, and further that the expanded gas may be used to cool the compressed gas by means of any heat interchanger.

In most of the processes now in successful work all the necessary steps are comprised in the above enumerated steps, which are old, as disclosed by expired patents.

It is unfortunate that in the Government publications particularly "Technical Paper No. 10 of the Bureau of Mines," entitled "Liquefied Products of Natural Gas," published in 1912, no mention is made of the above patents, though an extensive bibliography is given in the back of the pamphlet of which very little before 1911 refers to natural gas. The knowledge of the contents of the above patents throws a light on the patent situation which cannot be gained from any of the references cited in the bulletin.

The existing patents will not be criticised in any way except to state that they must all be construed in the light of the previous art as shown by patents above cited which have expired.

Among the earlier unexpired patents is No. 668,197 of 1901, issued to Le Sueur, which claims a process of liquefying "methane" from natural gas. The process described would not seem to liquefy methane, but it would liquefy the higher hydrocarbons of the methane series found in the gas. This is shown by the following statement occurring in the patent: "For instance, the liquid may be produced in the first place (from natural gas) by high pressure and fractional distillation induced thereafter by relief of pressure." This patent therefore discloses the compression of natural gas and a subsequent fractional distillation of the liquids produced. This would seem to disclose a system of producing different liquid products by fractional distillation after condensation.

While the disclosure quoted is in the specification and not in the claims it is sufficient to invalidate any subsequent patents which might broadly claim this process.

In 1907 patent No. 867,505 was granted to Dennis Hastings and W. Brink. It discloses that natural gas "after being artificially compressed" is brought into contact with water which serves to cool the gas; later "water or oil" is "atomized" to "intermingle with the gas" to cool it. This discloses the use of a "washing oil" to condense the lighter oils of the gas. It further discloses separating the cooling fluid and the condensed gasoline. This process is not claimed, but is an estoppel of later patents. The claims are for an arrangement of apparatus.

In 1909 John L. Gray obtained a patent, 993,976, for certain apparatus for obtaining casinghead gasoline from the gas. The claims are for an organization of apparatus for separating, first, any engine or cylinder oil from the gas by means of the ordinary steam trap or oil trap used on steam lines; a condenser with another oil trap beyond and a relief valve which is an ordinary steam safety valve. There is also a pot steam trap to separate the condensed gasoline from the gas and a receiving tank.

Subsequent patents will not be commented upon, the intent of this article being to point out the things which are undoubtedly old in the art and which are free to the public.

H. O. Chute.

197 Pearl Street, New York City.

## The Iron and Steel Market

The buying movement in steel products referred to in last report has proved to be as satisfactory in results as was expected, since by early February it brought the steel mills up to an operation at an average of about 70 per cent of capacity, and this rate was maintained throughout the month, comparing with an average operation of about 55 per cent in January and an average of less than 50 per cent in December.

In February strictly new buying decreased somewhat, indicating, with the fact that the mills did not move up to operating at full capacity, that the increased buying of January was rather a temporary movement, caused chiefly by the fact that buyers acquired confidence in prices, after a decline of many months, and covered both to replenish their stocks and to provide a moderate tonnage for the future. A large part of the business booked was in the form of definite orders, with specifications attached, but there was also a fairly large volume of contracting, chiefly for first quarter, but in the case of bars, plates and shapes the majority of contracts were made to run through the second quarter also. Specifications against such contracts have been good during February, and the total volume of specifications for all steel products in February probably exceeded the aggregate for January, though as the latter part of January was much more active than the fore part, the average of February probably did not indicate as much pressure as the latter part of January.

With market conditions as they are at present the mills are not promised a heavier operation than 70 or 75 per cent in March or April, but in most quarters the interest of buyers in the market is expected to increase as time passes. The advent of spring is expected to bring heavier consumption in general, while it is believed that the railroads will soon have to buy more freely than they have in recent months. Thus far this year railroad material is estimated to have constituted between 10 and 15 per cent of the total tonnage purchased, whereas the normal requirements are estimated at about double this proportion. The matter of railroad buying is generally held to hinge upon the treatment accorded the railroads by the Interstate Commerce Commission, and particularly as to the case of the eastern railroads, demanding permission to make a general advance of about 5 per cent in freight rates. It is possible that the influence of the expected decision is being overestimated, as to its effect upon railroad policy in the long run, though there is no question that on account of the pendency of the advanced rate case the railroads adopted a definite policy of holding back their orders. While the advanced tariffs have been suspended until September 12, there is reason to expect a decision between May 1 and July 1, and there is increased expectation that some advances, if not the entire 5 per cent asked, will be allowed.

Monday, February 2, a great many announcements were made of advances in steel products. Some of the indicated advances held, while some did not. The American Steel & Wire Company advanced its prices $1 a ton, to a basis of $1.60 for nails, and the independents followed. About January 1 there had been a short period in which business was done on a basis of $1.50, the market later advancing to $1.55, and the effect of the advance to $1.60 has been to bring in specifications on $1.55 contracts. The National Tube Company advanced standard steel pipe one-half point, the independents promptly following, and this advance has had the effect of greatly increasing the volume of specifications on old contracts. Oil country goods were also slightly advanced. The majority of large steel producers announced an advance in bars, plates and shapes, naming 1.25c. as their lowest quotation on these products, for early delivery, with 1.30c. for second quarter contracts. It quickly developed that business could still be booked at the lower level, in the case of attractive tonnages, while second quarter contracts could be placed at 1.25c. The Carnegie Steel Company, however, did not recede, and still maintains 1.25c. as its minimum, while it will not sell farther than three months ahead, except on specific jobs. On bars and plates the 1.20c. price can easily be done with several mills for early shipment, while on structural shapes such a quotation is relatively infrequent.

### Pig Iron

The buying movement in pig iron which was clearly marked in January extended into the first week or two of February, the market afterwards becoming decidedly quiet. The buying was sufficient to advance the market fractionally, but was not of sufficient volume to require the blowing in of any number of idle furnaces. Resumptions of blast furnaces to date have been almost exclusively of steel works furnaces. It would appear that consumers as a rule are covered to April or July for tonnages equal to their present rate of consumption, while the operating furnaces are equally well sold up. There is no prospect of consumption decreasing, while any considerable increase would doubtless require the blowing in of additional furnaces, stocks being very light. The great majority of the furnaces now idle blew out before the market had reached a level as low as at present, hence it seems fair to assume that before many of them blow in a decided advance will be required. Coke has proved stronger than expected, while Lake Superior ore for the 1914 season may bring about as much as in 1913, whereas late last year the expectation was that there would be a reduction to the 1912 schedule, this meaning 65 cents reduction on Bessemer and 55 cents on non-Bessemer. The decline in pig iron seems to have discounted such a reduction in ore, and if a smaller reduction is made, or no reduction, the tendency would be for pig iron to advance. The market stands quotable as follows: No. 2 foundry, f.o.b. Birmingham, $10.50 to $11.00; No. 2 X foundry, delivered Philadelphia, $15.00 to $15.25; No. 2 foundry, f.o.b. furnace, Buffalo, $13.00 to $13.25; No. 2 foundry, delivered Cleveland, $13.75; No. 2 foundry, f.o.b. Chicago furnace, $14.00; at valley furnaces (90 cents higher delivered Pittsburgh); Bessemer, $14.25; basic, No. 2 foundry and malleable, $13.25; forge, $12.75. Imported ferromanganese has been advanced by stages from $35 to $39, Baltimore, with $2.16 freight to Pittsburgh.

### Steel

About the beginning of the month the leading mills advanced prices on billets and sheet bars a dollar a ton, to $21 for billets and $22 for sheet bars, with $1 additional for second quarter, f.o.b. maker's mill, Pittsburgh or Youngstown. A few odd sales have been made at these advanced prices, but in general consumers are well covered to April 1 and in exceptional instances there are contracts to July 1. Forging billets have stiffened materially and are generally held at about $26, Pittsburgh. Rods are $26, Pittsburgh.

### Finished Steel

Prices named below are f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard section, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill except Colorado.

Plates, tank quality, 1.20c. to 1.25c.

Shapes, 1.25c.

Steel bars, 1.20c. to 1.25c., base.

Iron bars, 1.35c., Pittsburgh; 1.27½c. to 1.32½c., Philadelphia; 1.12½c. to 1.15c., Chicago.

Wire nails, $1.60 per keg, base; plain wire, 1.40c., base.

Sheets, blue annealed, 10 gage, 1.40c. to 1.45c.; black, 28 gage, 1.95c. to 2.00c.; galvanized, 28 gage, 2.95c. to 3.00c.; painted corrugated, 28 gage, 2.15c. to 2.20c.; galvanized, corrugated, 28 gage, 3.00c. to 3.05c.

Merchant steel pipe, ¾ to 3-in., 79 per cent. off list.

Steel boiler tubes, 3½ to 4½-in., 71 per cent. off list.

Standard railroad spikes, 1.45c. to 1.50c. Pittsburgh, 1.50c. to 1.55c., Chicago.

Structural rivets, 1.70c.; boiler rivets, 1.80c.

Cold rolled shafting, 64 per cent. off list.

---

## The Western Metallurgical Field

### Developments at Leadville

Ever since the discovery of zinc carbonate ore at Leadville there has been talk about building a treatment plant there to handle the low-grade ores that could not be shipped to the smelters in the Middle West. It is definitely known that there is a considerable tonnage of such ore, containing from 14 to 18 per cent zinc, that has not been salable. In the aggregate it could support a treatment plant, provided a profitable metallurgical scheme could be devised, and several individuals and companies have considered the feasibility of entering this field. Hydrometallurgical processes have been tested, and pyrometallurgical concentration prior to smelting also has been proposed.

Within the past thirty days, however, the possibility of erecting a treatment plant at Leadville has assumed more definite shape, and as the project is in the hands of experienced zinc smelters it is receiving more serious attention than has been given to previous proposals. Messrs. Augustine and Jones, formerly associated with the American Metal Company's zinc smelters at Collinsville and Bartlesville, Okla., have visited Leadville on a trip of inspection of the mines. It is reported that they have contracted for the ore supply from at least one mine, and have investigated possible sites for their plant. They propose to produce zinc oxide from low-grade carbonate of zinc, but the details of their process have not been announced. The commercial phase of the matter is all-important, and probably has received the careful attention of the promoters. If the plan is carried out the plant will be erected this summer and be in operation by fall.

Prospects are again bright for the unwatering of some of Leadville's older mines, particularly the downtown district. A new scheme is being promoted by ex-Governor Jesse F. McDonald, who is securing long-time leases on mines in the vicinity of the Penrose shaft, with the intention of pumping water at that point.

### Organizations of Mining Men

Colorado and Utah mining men have organized for the purpose of securing for the mining industry the recogniation which they feel is due to the leading industry of those states. The meetings, which were held in Salt Lake City and Denver, occurred too late to be reported in this issue. It is a regretable fact that mining men have not stood together in matters relating to their industry, with the result that legislatures have passed inane laws vitally affecting mining in an adverse way. One particularly flagrant sample of this is the mine taxation law passed by Colorado's last legislature, without so much as a serious protest on the part of mining men. Their attention was called to the bill, but they regarded it as too outrageous to be considered seriously. Apparently, however, nothing is too foolish or unfair to get past some of our legislative bodies if there is no concerted protest. Mining men have only themselves to blame if they do not unite to create a strong sentiment in favor of a fair recognition of their industry, and it is hoped that something good will come out of these efforts in Utah and Colorado.

### Prospecting for Carnotite

The proposed action of the federal government in withdrawing carnotite deposits from private exploitation has resulted in a rush of prospectors to the districts where these ores have been found, also in the "discovery" of several new districts. A great deal of this feverish excitement has been created and fostered by the daily papers, which have printed the most absurd statements regarding the value of the ore and the extent of the deposits. Thus, for example, one district is said to contain "100,000,000 pounds of radium ore which will make between 100 and 150 ounces of radium, worth more than $900,000,000." The Colorado deposits, we are informed, are low-grade, and consequently are converted into "pitchblende ingots" before shipping East. With such glittering prospects held before the uninitiated, it is not surprising that they have been induced to search for this newest El Dorado. That they will return rich in experience and with a dubious regard for radium is a foregone conclusion.

The production of uranium, vanadium and radium in 1913 has been reported by F. L. Hess, of the Geological Survey. Fifty tons of pitchblende containing 1.49 per cent $U_3O$ was shipped from the Kirk mine in Gilpin county, Colorado. The Belcher and Calhoun mines in the same district sold only a few pounds of the same mineral. The shipments of uranium and vanadium were equivalent to 38 tons of $U_3O$, and 914 tons of $V_2O$. These quantities are equivalent to 32.3 tons metallic uranium and 412 tons metallic vanadium. The recoverable radium from the uranium ores is estimated at 9.79 grams of metal, worth $120 per milligram, or a total value of $1,055,000. The value of the carnotite ores sold was about $142,000, which represents the uranium value only, as little or nothing was paid for vanadium. The production for 1913 was the largest yet made.

### Copper Hydrometallurgy

Among the companies now investigationg the hydrometallurgy of low-grade copper ores is the Nevada-Douglas, owning mines in Nevada. Tests have been under way in Denver at the plant of John E. Greenawalt, and while the work is not yet completed the results are very encouraging. The company has recently made public the statement that the cost of electrolytic precipitation is 1.38 cents per pound of copper, and gives an estimate of 8 cents per pound as the probable total cost of producing copper, including mining, treatment and freight charges. The Greenawalt cell differs from others in having the electrodes arranged horizontally instead of vertically, with only one anode and cathode in each shallow vat, the anode being uppermost and only slightly submerged. The solutions are saturated with sulphur dioxide prior to electrolysis.

### The Bureau of Mines and Utah

About a year ago Utah provided for the establishment of a metallurgical research department at the School of Mines of its State University, the purpose of the department being "to conduct experiments and researches, either alone or in cooperation with the National Bureau of Mines and other agencies, with a view to finding ways and methods of profitably treating low-grade ores, of securing a higher percentage of extraction of metals from their ores, and of obtaining other information that shall have for its object the benefit of the mining industry." Almost a year elapsed before a beginning was made to carry out the provisions of the law. Recently the Bureau of Mines sent Mr. Dorsey A. Lyon and Mr. Robert M. Keeney to Salt Lake City to start the work, and it is now under way.

### Quicksilver In Nevada

At Ione, Nev., the Nevada Cinnabar Co. has completed a modern plant for the treatment of mercury ores, and expects to commence operations this month. The company owns about 600 acres of land from which the ore will be mined by quarrying from open pits. The plant is operated throughout by electric power, and the furnace has a capacity of 50 tons daily. It is expected that ore containing 1 per cent mercury will be handled profitably.

### Company Reports

**The Portland Gold Mining Co.** reports unusually satisfactory results from its operations during 1913. The net earnings amounted to $604,443, of which $300,000 was paid in dividends. Ore mined and shipped to the remodeled mill at Colorado Springs amounted to 53,245 tons, of an average value of $25.93 per ton. The mine also produced 127,054 tons of low-grade ore, much of which was taken out in course of development. This, together with 51,108 tons of low-grade ore taken from the dump, constituted the material treated in the new Victor mill. The average assay value of this material was $2.95 per ton. Extensive development is planned this year for the seventeenth level of the mine. The Roosevelt drainage tunnel is lowering water in the mine at the rate of about 8½ feet per month, and will drain the property to a further depth of 500 feet. The Victor mill was enlarged during the year by the addition of an ore-bin, Chilean mill and eight concentrating tables. The report does not contain as complete data as usual on metallurgical operations.

From the quarterly reports of the **Nevada Consolidated, Chino and Utah** copper companies for the fourth quarter of 1913, the following data are tabulated:

| | Nevada Con. | Chino | Utah |
|---|---|---|---|
| Ore milled, tons..... | 833,989 | 429,750 | 2,113,080 |
| Per cent copper..... | 1.58 | 2.08 | 1.22 |
| Copper produced, lb. | 16,684,955 | 12,021,872 | 23,884,467 |
| Cost copper per lb., c. | 8.63 | 9.17 | 8.93 |
| Extraction, per cent. | .... | 65.54 | .... |

**Camp Bird, Ltd.**, has issued a circular regarding conditions at the Santa Gertrudis mine in Mexico, in which it is stated that while the internal conditions in Mexico have not as yet affected the company's operations, it is deemed advisable to pass the half-yearly interim dividend in order to be able to meet any unforeseen contingencies.

The earnings have been ample to meet the dividend as usual, but it is deemed prudent not to disburse the same.

# Mechanical Refrigeration—II

## The Compression Refrigeration Cycle

BY H. J. MACINTIRE

The compression refrigeration cycle will not appear complicated if the essential duty of the machine is held in mind. It should be understood first that vapors only are used as refrigerating mediums and more particularly ammonia and carbon dioxide. These vapors are made to condense and form a liquid by being compressed sufficiently to allow of condensation with the cooling water present. The condensing pressure varies directly with the temperature of the cooling water, though the ratio is different for each vapor. Cooling water is absolutely essential and the cooler this water the more readily the vapor can be condensed.

Refrigeration is obtained by allowing the liquid refrigerant to abstract heat from its surroundings—the pressure under which the vapor does this being arranged as desired. The boiling temperatures of water under one atmospheric pressure is 212° Fahr., but under 150 lb. gage pressure it is about 365.6° Fahr. In like manner the temperature under which ammonia boils when its pressure is one atmosphere is — 26.8° Fahr., but at 15 lb. gage the boiling temperature becomes — 0.8° Fahr. Refrigeration, as we understand it, is simply the removal of heat at a temperature below that of the atmosphere. If a body is colder than the surroundings, heat flows from these surroundings to the cold body. Refrigeration may require, then, either the lowering of the temperature of a body below the atmospheric temperature or the maintaining of this low temperature.

In other words, the liquid refrigerant is allowed, then, to boil at such a pressure as will give the required temperature to the refrigerated object. This pressure is under the control of the engineer, by proper adjustment of the speed of the compressor and of the liquid refrigerant passing into the cooling coils.

### THE REFRIGERATING CYCLE

Because an expensive refrigerant (or working fluid) is used—usually ammonia or carbon dioxide, as just mentioned—the refrigerating cycle is a closed one, and the fluid is used continuously. The cycle of operations, being composed of heat exchanges, can best be represented by a heat diagram as shown in Fig. 1. The ordinates are temperatures in degrees Fahrenheit absolute (zero ordinate being the absolute zero) and the abscissa are so chosen that an area on the diagram represents heat units in B.t.u.

The point 2 corresponds to the admittance of the liquid to the refrigerating coils. The pressure on the liquid had been that of the condenser, and in the cooling coils it is the so-called back pressure—an amount considerably lower. Point 2, then, corresponds to the expansion valve of the refrigerating cycle. During the drop of pressure the temperature has to decrease also according to the physical laws just mentioned. The only way in which this decrease of temperature is possible is to have a part of the liquid evaporated.

In the diagram 120 is a line representing the condition of the liquid, whereas *7P* corresponds to that of a dry saturated vapor. The region between these two lines represents the condition of saturation. Evidently, then, a pound of the liquid refrigerant may be represented by some point as 1 on the liquid line. If heat is added and evaporation begins, heat will be supplied at constant temperature until all the substance is evaporated, and the process may be represented by the point moving from 1 to 7. The heat added (called the latent heat of vaporization) is found to be equal to the area below the line 17. Likewise the region to the right of *7P* is that of superheat—an intermediate condition between that of saturation and of a perfect gas.

As the liquid passes the expansion valve at 2, then, it enters a condition of lower pressure and lower temperature, and a certain amount of the liquid, some 5 per cent to 15 per cent, is evaporated in order to lower the temperature of the remainder. Subsequent evaporation in the cooler is at $t_3$ and is equal in heat units to the area under the line *3P;* that is, the area *3PS8* is equal to the heat added (refrigerating effect) by the goods.

### WET COMPRESSION

As refrigeration progresses the liquid is changed into a saturated or slightly superheated vapor which must again be returned to the condition of a liquid. The compressor serves this purpose. The remainder of the cycle, however, depends on the details of the compression as far as the capacity of the installation and the efficiency of operation are concerned. The wet compression—so-called—permits a small amount of liquid ammonia to pass into the cylinder of the compressor with the vapor. During compression the temperature of the vapor begins to rise, a tendency which is partly neutralized by the liquid injection, the latter absorbing heat by evaporation similar to the action of water in the old-style wet compression for compressed air machinery. If a large amount of ammonia is admitted the compression stroke may be represented theoretically by the line 47, but the usual wet-compression line is shown by 56, giving some 40 deg. of superheat at the point 6.

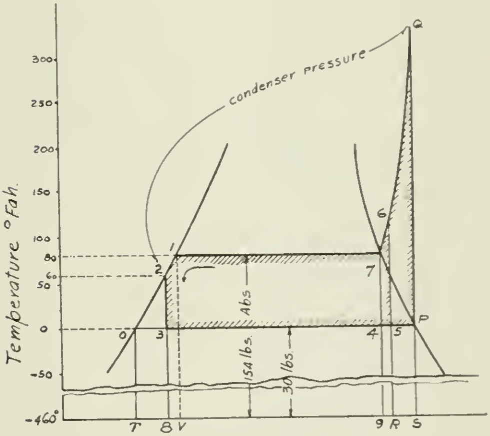


FIG. 1—REFRIGERATING CYCLE

### DRY COMPRESSION

Another, and by far the more common method of operation, is to allow dry or slightly superheated vapor to enter the cylinder, which in this case is water-jacketed. The temperature at the end of compression is quite great, often 300 deg. Fahr. to 350 deg. Fahr., but full refrigerating effect is obtained from the ammonia, giving in Fig. 1 a theoretical advantage over the wet compression of 11 per cent and 8 per cent respectively. There are other operating factors which give decided advantages to the dry-compression cycle, such as greater volumetric efficiency, greater allowable piston speed, etc.

The compressed vapor is now exhausted into coils in metal contact with water. The water cools the refrigerant to approximately its own temperature during which time the heat due to the superheat *Q*79*S*, the heat of condensation 71*V*9, and part of the heat of the liquid 128*V*, are abstracted, thus bringing the substance back to 2, which was the point given as the beginning of the cycle. The refrigerating cycle, then, consists of a drop of pressure at the expansion valve, the evaporation at the refrigerating temperature, the compression, and finally the condensation at the upper pressure.

### INDICATOR CARD

Let us consider the cycle from another standpoint—that of the work performed per compressor stroke. If we plot the pressures in the cylinder for various positions of the piston, the indicator diagram shown in Fig. 2 is obtained. Here, in contradiction to Fig. 1, the area of the enclosed figure is the work done by the piston on the vapor, and this is proportional to the total power supplied. It is usually important to keep this supplied power down to a minimum, and to do so certain things, as with air compressors, must be avoided. These are wire drawing through the suction valve, excessive resistance to the vapor passage through the discharge valves, the valve ports and discharge pipes, and finally in the obtaining of as flat a compressor curve *ac* as is possible.

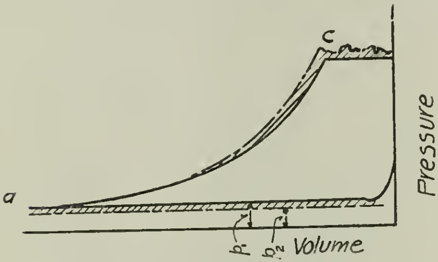

FIG. 2—INDICATOR DIAGRAM

The compression curve has been given considerable attention and the compressors using oil or ammonia injection as a rule have a flatter curve than those using the water jacket only. The tendency at present, however, is to increase the piston speed; this fact alone would cause the former method to be abandoned as it was for air compressors twenty or thirty years ago. Although a maximum pressure of from 200 to 225 pounds is frequently obtained during compression, yet multi-stage compression for refrigeration is not used because of mechanical difficulties and the decided variation of the discharge pressure with change in the temperature and the quantity of the condensing water.

The shaded areas at the top and the bottom of the indicator card may be decreased by care in the design of the valves. Mechanically operated valves have not yet been used, even for the inlet stroke. The desirable net area of the inlet valve depends on the piston speed, and should be from 4 to 8 per cent of the piston area. In air compressors and blowing engines the suction valves frequently have from 14 to 20 per cent of the piston area, but these high values are for high piston speeds, much above the present refrigerating practice. The pressure $p_1$ corresponding to the suction pressure in the compressor should not be much greater than $p_2$ corresponding to the cooler pressure. Differences of pressure much over one pound should be investigated critically, likewise the maximum compressor pressure should not be much greater than the condenser pressure for the same reason.

### CONDENSER PRESSURE

The condenser pressure depends directly on the temperature and the amount of the cooling water. Without cooling water refrigeration is practically impossible. As is seen in Fig. 2, the work of compression increases with an increase of condenser pressure, which is a little less than the discharge pressure from the compressor. It is, therefore, very desirable to use as cool condensing water as is possible, especially where use is made of motor-driven compressors.

Table I, which is the result of considerable experimentation, is taken from the Proceedings of the American Society of Refrigerating Engineers, 1906. In this table it is seen that one gallon of water per ton of refrigeration (a refrigerating effect equivalent to the abstraction of 200 B.t.u. per minute) at 60° is nearly equivalent to 1½ gallons at 70°, two gallons at 75° or three gallons at 80° F. As electric motor-driven compressors are becoming increasingly popular, the desirability of cool condensing water is very apparent.

TABLE I. AMOUNTS OF COOLING WATER

*Table I—Amount of Cooling Water*

| Initial Temperature of Cooling Water. | Gallons of Water per Minute, per Ton. | | | | | |
|---|---|---|---|---|---|---|
| | ½ | ¾ | 1 | 1½ | 2 | 3 |
| 50° F | 226 | 163 | 137 | 114 | ... | ... |
| 55 | 245 | 178 | 150 | 126 | ... | ... |

| Range | 56 | 37 | 28 | 18.7 | 14 | 9.3 |

Liquid Refrigerant at Expansion Valve = 68° F.

Figures in table are condensing pressure in pounds per square inch gage.

The suction pressure, as already mentioned, is at the command of the operator and should be governed by the work to be performed. For instance, if air cooling down to 50° F. is desired, the boiling temperature of the refrigerant should be about 20 to 30° F. and not 0° or lower. The reason for this is to be found on the consideration of the specific volume at these temperatures. The volume of one pound of ammonia at 30° is 4.82 cubic feet, and at 0° it is 9.19 cubic feet or an increase of necessary displacement of the compressor (in work done and in capacity as well) of a little over 90 per cent. An advantage, however, is obtained in using the lower boiling temperature as far as the condenser is concerned, as the greater temperature difference on the two sides of the condenser pipes will allow a smaller area of condenser. The great increase in operating cost is apparent from what proceeds, however.

University of Washington,
Seattle, Wash.

---

**Tungsten ores were produced** by six western states in 1913—Colorado, California, Idaho, Arizona, South Dakota and Nevada. Boulder county, Colorado, was the largest producer, with an estimated output of 953 tons of ferberite. The total production for the United States was equivalent to 1525 tons of ore, carrying 60 per cent tungstic acid, $WO_3$. The Atolia district, California, was the second largest producer, and was the first in rank of scheelite producers. Prices generally ranged from $6 to $7.50 per unit of 20 lb. of $WO_3$, and were higher than in 1912.

**Concentration tests on Mesabi iron ores** have been made at the experiment station of the Minnesota School of Mines, and reported in Bulletin No. 2. A wide variation in grade of concentrates from crude ores of practically the same grade seems to indicate that the texture and character of the several sizes of material composing the crude ore are the criterion of washability, and not their chemical analysis.

# The Manufacture and Uses of Blaugas

BY DR. HUGO LIEBER

William Murdoch's invention in 1792 of a process for the manufacture of an illuminating gas, and the first establishment of a commercial gas plant in Birmingham ten years later was destined to be rapidly developed and perfected, so that it soon became a commercial necessity. However, one of the disadvantages of this invention was the fact that it required a considerable investment of capital for the manufacturing plant and its maintenance, and especially for the equipment of gas mains required to conduct the gas to the consumer. Therefore, it was soon recognized that a gas factory could be commercially and successfully operated only in such districts which were thickly populated, and where a large number of customers could be connected with the gas mains and thus be made consumers of this commodity.

The great advantages derived from the use of gas were soon recognized and created a considerable demand for same, but owing to the limitations of a supply of gas to the territory traversed by the gas mains, and as beyond reach of these there was soon created a great and constantly growing demand for this commodity, many attempts were made to fill this demand.

These experiments resulted in various inventions of more or less value, having for their object the production of a compressed or condensed gas in such form that it would be commercially transportable beyond the reach of the gas mains.

In the experiments conducted by various investigators, coal gas as well as oil gas was used, but attempts to produce a commercially condensed and transportable coal gas were soon abandoned in favor of oil gas on account of the higher calorific value of the latter. The compressed oil gas is to-day still used very extensively, especially for lighting of railroads, buoys, lighthouses, etc.

The compressing and commercially adopting of such compressed oil gas was successfully done especially by Pintsch, and with such compressed oil gas is usually identified the name of Pintsch owing to the great introduction of the Pintsch system throughout the world, and such compressed oil gas is usually known as Pintsch gas.

Under the Pintsch system the oil is distilled at fairly high temperatures (900 deg. to 1000 deg. C.) so as to produce as large an amount of fixed gases as possible. These fixed gases are subjected to a pressure ranging from 5 to 16 atmospheres, in the United States 6 atmospheres being the prevailing pressure. As under the Pintsch system, after distillation and compression certain of the hydro-carbons are liquefied, these have to be removed, and only the remaining gaseous compressed hydro-carbons are permitted to enter the shipping containers.

A German chemist, Herman Blau, succeeded in making a great improvement in the production of a transportable compressed oil gas. He compressed oil gas to such a degree that the bulk of same was liquefied. The process employed by Blau is in brief as follows:

In the original process gas oil is conducted into the retorts the same as in the manufacture of Pintsch or other oil gas, and is vaporized and decomposed in these retorts under a temperature of about 550 deg. C. to 600 deg. C. This low temperature is employed in order to prevent the production of a large percentage of fixed gases, as contrary to the heretofore existing principle it was the desire of Blau to produce as large a quantity of the coercible hydro-carbons and as small a quantity of the permanent gases as possible. After the oil has thus been distilled, the gas obtained is conducted in the usual manner through hydraulic mains, coolers, cleaners and scrubbers in order to remove the tar which these gases contain. After this the gas is purified of its chemical impurities by being forced through chemical cleansing agents, where especially sulphide of hydrogen and carbon dioxide, etc., are removed. This being completed, the gas is conducted in the usual manner into large gas holders for storage purposes. With the exception of the difference in the temperatures employed in the distillation process, the Blau process up to this point does not vary materially from any of the other well-known processes of oil gas distillation employed heretofore.

Since its first introduction, the Blau process has been very materially and rapidly improved from time to time, these improvements having for their object the production of a better quality or a drier gas, and also the greater yield from a certain quantity of oil. In the original process as employed by Blau, the gas from the holder was drawn into a cooler where, under a suitable process, it was cooled considerably below zero in order to liquefy and discard at this stage certain of the coercible hydro-carbons which, in the finished product, were not desired; that is, such hydro-carbons which under normal pressure and temperature would again liquefy.

Under the new process as it is employed in the various Blaugas factories at the present time, this preliminary cooling has been discarded. The gas is drawn directly from the holder into the compressor which is usually a three-stage or four-stage compressor. The liquefying and discarding of those coercible hydrocarbons which are not desired in the final product now takes place in the first and second stage of the compressor, and the balance of the gas passes on into the third and eventually the fourth stage where the gas is compressed up to 100 atmospheres. During all stages of the compression water is injected into the compressing chambers for lubricating and cooling purposes. The water which is carried over after the final compression is separated from the liquefied hydrocarbons after the last stage of compression, and is then withdrawn from these by a suitable device. The refuse tar obtained from the cooled and scrubbed gases is collected in proper receptacles, and from there is pumped into tanks from where it flows by its own gravity to the retorts where, with compressed air or steam, it is sprayed under the retorts, and is thus used to supply all the heat required for these retorts.

As in the course of the manufacture and during the distillation of the oil a certain amount of permanent gases have been produced which the liquefied hydrocarbons have been unable to absorb, these permanent gases are conducted into large cylinders from which, by means of proper reducing and regulating valves, they are conducted into the engine where they produce all the power which is needed in a Blaugas plant.

The whole Blaugas process, as it is now employed, is so minutely worked out that but a very slight excess of tar and permanent gases is obtained beyond the quantities required for heating and power purposes. The final product consisting of liquefied hydro-carbons, and absorbed therein or dissolved thereby non-liquefied hydro-carbons, is of such composition that this whole aggregate will remain a liquid as long as same is under the pressure employed in the process, but these liquefied hydro-carbons will at once become converted into a gaseous aggregate if the pressure is reduced to approximately atmospheric pressure. These liquefied hydro-carbons are conducted into suitable steel cylinders or bottles for transportation purposes.

Under the compression of 100 atmospheres the oil gas is reduced to 1/400 of its volume, the gas so obtained being of a specific gravity which is approximately the same as atmospheric air. One ltr., that is, 1.246 gr. of Blaugas at 0 deg. C. and 760 mm barometer contains 1.042 gr. carbon and 0.204 gr. hydrogen. This gas has a calorific value of about 1800 B.t.u. per cu. ft., or approximately three times the heat value of ordinary city gas.

The explosive range of Blaugas is lower than that of any other commercial illuminating gas, which the following table will show:

| | FROM | TO | EXPLOSIVE RANGE |
|---|---|---|---|
| COAL GAS.... | 6.33% gas<br>93.67% air | 19.33% gas<br>80.67% air | 13% |
| ACETYLENE. | 2% gas<br>98% air | 49% gas<br>51% air | 47% |
| HYDROGEN.. | 9.5% gas<br>90.5% air | 66.3% gas<br>33.7% air | 56.8% |
| BLAUGAS..... | 4% gas<br>96% air | 8% gas<br>92% air | 4% |

As has been stated before, the heat value per cubic foot of Blaugas is about 1800 B.t.u., whereas that of acetylene is 1500 B.t.u. per cubic foot and of hydrogen 425 B.t.u. per cubic foot. As the volume of Blaugas is reduced to 1/400 under its compression, it requires much smaller receptacles to transport a certain number of heat units with Blaugas than with any other gas.

Of the commercially transportable gases are to be considered acetylene, hydrogen and Blaugas, as Pintsch gas is a transportable gas in a limited sense only. Acetylene can be considered as a transportable gas only under the so-called "Acetylene Dissous" system. The following table will show the heat value per cubic foot, the container capacity, the weight of containers required for a given number of heat units, the number of containers required, and the price per 100,000 B.t.u.:

| | HYDROGEN | ACETYLENE DISSOUS | BLAUGAS |
|---|---|---|---|
| Heat value, per cu. ft.... | 425 B.T.U. | 1500 B.T.U. | 1800 B.T.U. |
| Contents of a container of 1 cu. ft. water capacity | 120 cu. ft. | 100 cu. ft. | 300 cu. ft. |
| Weight of containers required to transport a given quantity of heat units (for example 540,000 B.T.U.) ....... | 1060 pounds | 432 pounds | 100 pounds |
| Number of containers required to ship 5,100,000 B.T.U. ................ | 106 | 36 | 10 |
| Price for 100,000 B.T.U.. | $1.41 | $1.00 | 44c. |

Hydrogen per cu ft., 3/5c.
Acetylene Dissous per cu. ft., 1½c.
Blaugas, per cu. ft., 4/5c.

Blaugas is transported in steel cylinders of various dimensions ranging in size (water capacity contents) of from ¼ ltr. to about 100 ltrs. The size mostly used is a cylinder with a water capacity of about 27 ltrs., or about 1 cu. ft. This cylinder when properly filled contains about 20 lb. of Blaugas, which will become converted into about 250 cu. ft. of expanded gas when the pressure is released. As Blaugas contains no carbon monoxide it is a non-poisonous gas.

Blaugas is used mostly in such districts where no gas is supplied from a central gas plant through ordinary mains, but it is also used very extensively in districts where city gas is supplied, especially for steel and cast-iron welding and cutting, brazing, soldering, for laboratories and such purposes where a uniform gas with high heat units is essential.

In districts where gas is not supplied through mains or through a central plant, Blaugas is used for all purposes where otherwise city gas is used, namely, for illuminating, cooking, ironing, heating, and similar purposes.

The cylinders are attached by means of a reducing valve to a small expansion tank, and from there the gas is conducted into the pipe line by a pressure regulator. As Blaugas is under a high pressure when delivered to the consumer, it is a very simple matter to produce so-called pressure gas wherever same is required, pressure gas being very desirable for the production of brilliant illumination, one c.b.f. of Blaugas producing 80 candles in an incandescent Welsbach burner.

The first Blaugas factory was erected in Augsburg, Germany. This was rapidly followed by other factories in Budapest, Copenhagen, Bucharest, St. Petersburg, and Hoek von Holland. In the United States at the present time there are factories in Long Island City, St. Paul, Kansas City, Omaha, and Portland, Me. There are a number of factories now in course of construction.

## Notes on the Gran-Annular Electrical Furnace

BY ZAY JEFFRIES

This is the name which has been given to the electric furnace invented by C. H. Fulton and W. A. Coursen. The name implies "granular" because the electric resistor is in the form of grains and "annular" because the grains occupy a space in the furnace the shape of a hollow cylinder. The furnace was described in 1912 by C. H. Fulton in connection with the investigation of slag.[1] Since then a few mechanical improvements have been made and considerable work has been done to ascertain the most suitable kind and size of resistor to use.

### Description of Furnace

Fig. 1 shows the Gran-Annular electric furnace in cross-section. The essential features are given by the inventors as follows: (1) Two concentric cylindrical tubes, the inner one of which forms the heating-chamber, made either of magnesia or alundum, and the cylindrical space between which, when filled with a granular resistor, becomes the resistor cylinder. (2) A resistor of uniform cross-section throughout its length. (3) The positive and firm insertion of the tubes in the electrode plates, thus maintaining the resistor chamber in perfect shape. (4) That any part can be readily and cheaply replaced. (5) Simplicity and compactness of construction, preventing racking and distortion during heating.

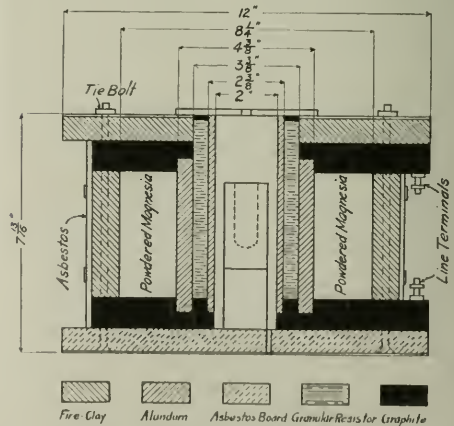

FIG. 1—CROSS-SECTION OF THE GRAN-ANNULAR ELECTRIC FURNACE

A furnace with the dimensions given satisfies most of the laboratory requirements.

---

[1] Transactions American Institute of Mining Engineers, Vol. XLIV.

### Resistors

Three materials are at present available, kryptol, granular carbon, such as is furnished by the National Carbon Company, and granular graphite, furnished by the Acheson Graphite Company. The curves in Fig. 2 show the variation in the specific resistivities of the three materials per cubic inch, with change in temperature. The furnace was used for the determinations. In each case the resistor was put into the furnace loose, i.e., with pressure due only to its own weight.

The hot junction of a platinum platinum-rhodium thermo-couple, protected by a quartz tube, was placed in the resistor, a distance from the top electrode equal to one-fourth the distance between the electrodes. The resistances were obtained by measuring the current and drop in potential between the electrodes.

Temperature and resistance readings were taken at the same time in fifteen-minute intervals. The temperature indicated by the thermo-couple is taken as the average of the resistor. That the average temperature was somewhat lower than the results given is highly probable for reasons that will appear later. The radiation of heat, however, is more active at the top electrode than at the bottom, a condition which tends to correct the error.

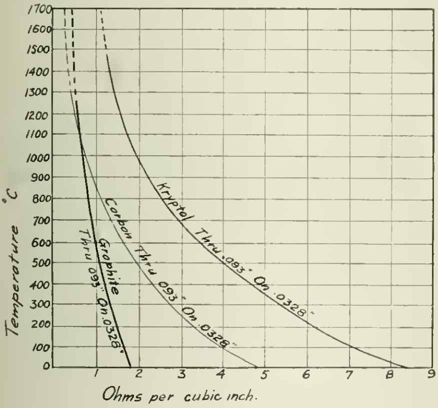

FIG. 2—TEMPERATURE, RESISTIVITY CURVES FOR KRYPTOL, CARBON AND GRAPHITE

One thing common to all of the materials is the marked negative coefficient of resistivity. The writer offers an explanation for this which fits the facts in the case very closely.[2] A discussion of the theory is especially invited. In the first place, Acheson graphite has a much more constant resistance than is indicated by the curve.[3] The decrease in resistivity must then be due to an increase in contact area between the grains. This is brought about by the expansion of the grains with increase in temperature, wedging preventing the displacement of the resistor mass as a whole, and thus decreasing the resistance. This may be compared to a carbon plate rheostat, the expansion of the grains being analagous to increasing the pressure between the plates with a hand wheel.

Considering, then, that the decrease in resistivity of graphite is almost entirely due to the better contacts between grains, why do kryptol and carbon show larger decreases? Kryptol is a mixture of carbon and some dilutent which is probably not a good conductor of electricity and also probably contains some graphite. Carbon itself has a marked negative coefficient of resistivity, which, in conjunction with the better contacts, makes the negative coefficient of kryptol much greater than graphite. With this theory in mind it would seem that carbon alone would have a greater negative coefficient than kryptol. That this is true is shown by an example taken from the curves.

| | Graphite | Kryptol | Carbon |
|---|---|---|---|
| 0 degrees C.......... | 1.80 ohms | 8.30 ohms | 4.80 ohms |
| 1200 degrees C.......... | 0.60 ohms | 1.60 ohms | 0.50 ohms |
| Ratio .................. | 3 : 1 | 5.18 : 1 | 9.6 : 1 |

At high temperatures in the presence of oxygen there is a condition which tends to increase the resistance. The contact points of the grains being the hottest will oxidize more readily than the cooler parts, and as wedging prevents the free settling of the grains by gravity, some of the contacts will have their areas reduced and others may be burnt out completely. With an excess of oxygen and at a very high temperature, this condition may overcome the negative coefficient and actually indicate an increase in resistance with an increase in temperature. This increase must be due to the reasons given because on cooling, the resistance increases further.

### Comparison with the Platinum Wire Furnace

When compared with the platinum wire furnace the gran-annular furnace has two unquestioned advantages. (1) The cost is less than one-third as much, and (2) it can be used safely at temperatures 300 degrees C. higher than the platinum wire furnace. The current control, however, is better in the platinum furnace because the resistance is the same no matter how many times the furnace has been heated. The resistance of the gran-annular furnace increases slightly every time it is heated above 1200 degrees C. This is caused by air gaining access to the resistor through the pores of the inside alundum tube, when the furnace is opened, and oxidizing some of the carbon.

When the resistance gets so high that a short circuit through the furnace does not give as high a temperature as is desired, the resistor is poured out and the furnace is refilled with the same material. A similar result can be obtained by packing the resistor, but since unequal packing causes hotspots, the former method is used. One filling usually lasts from forty to fifty heats to a temperature of 1500 degrees C. It takes about five minutes to change the resistor. Although the resistance changes from heat to heat, during any given heat the current can be controlled within very narrow limits.

The fact that granular resistors have negative coefficients of resistivity gives the gran-annular furnace two distinct advantages over wirewound furnaces. In both types the hottest part of the heating chamber is somewhere near the middle as a result of the greater heat radiation at the ends.[4] In the wire type, since the resistance of the wire is the greatest where the temperature is the highest, more calories of heat will be liberated per unit of length in the middle of the furnace than in any other part. Therefore, the most heat is liberated where it is least desired, thus increasing the difference in temperature between the middle and adjacent parts.

In the gran-annular furnace the hottest part has the least resistance and hence less heat is generated in the middle than at any other part of the heating chamber. In fact, there is an absolutely automatic adjustment tending to make the temperature uniform throughout the entire length of the resistor column.

The other advantage is the automatic regulation in starting the furnace. A furnace should be heated in about equal temperature intervals. A given number of watts will raise the temperature of a cold furnace several times as many degrees as will an increase of the same number of watts 1000 or 1200 degrees higher. The wattage should be progressively increased while heating. A wire furnace has its least resistance when cold and demands changing the external resistance while heating. The gran-annular furnace, having its greatest resistance when cold, can be started with a given external resistance (which will be considerably less than the resistance of the furnace) and as the temperature increases the wattage increases, due to the furnace resistance approaching the external resistance.

### Operation and Control of Temperature

The furnace can be used with either direct or alternating current. Where the latter is available any of the above-named resistors can be used, carbon and graphite demanding lower voltages than kryptol. A furnace having dimensions as given in Fig. 1 requires a pressure of 110 to 115 volts when kryptol is used. Since nearly all laboratories have alternating or direct current at this pressure, the use of lower voltages will not be discussed further. When direct current is used the Weston miniature precision ammeters and voltmeters are entirely satisfactory for watt measurements.

For the proper control of temperature, C. H. Fulton and the writer have designed a special rheostat. It consists of nineteen coils of resistance wire, each of which is connected to a separate single-throw switch. The first coil has a resistance of 6 ohms and a carrying capacity of 18 amperes, the reason for which will appear later. The second coil has a resistance (102 ohms) such that when connected in parallel with the first coil, their combined resistance is 5 2/3 ohms.

In this way the addition of each coil in parallel lowers the resistance 1/3 ohm, and adds as much carrying capacity as will result from the decreased resistance, until 1 ohm is reached, when each additional coil decreases the resistance ¼ ohm. Thus, when all of the coils are used at the same time, they have a resistance of ¼ ohm and a carrying capacity of 50 amperes.

A 50-amp. single-throw switch, used for short-circuiting the furnace, is also provided on the same switchboard. A current of 50 amperes is seldom needed, so the excess carrying capacity permits the cutting out of some of the intermediate coils to obtain small differences in resistance. For instance, when the first thirteen coils are in, the resistance is 2 ohms. The actual resistance of the second coil is 102 ohms and by disconnecting it the resistance of the twelve remaining coils becomes 2.04 ohms. Now, if the third coil, having a resistance of 91 ohms, be disconnected, the resistance of the remaining coils becomes 2.09 ohms.

In operating both granular-resistor and wire furnaces and in designing rheostats for same, this fact should be taken into consideration: that with a given external resistance, the watts consumed in the furnace becomes a maximum when its resistance is equal to the external resistance. If a furnace has a resistance, when cold, of 6 ohms and an external resistance of 4 ohms be used and the pressure is 110 volts, there will be 726 watts consumed in the furnace. As the temperature of the resistor increases its resistance decreases quite rapidly so that when the resistance of the furnace reaches 4 ohms it is receiving 757 watts, decreasing to 740 watts when a furnace resistance of 3 ohms is reached.

In taking critical points with a thermo-couple under these conditions a slight change in the heating rate may be noticed when the furnace resistance just equals the external resistance, which is due to the furnace and not to the sample under investigation. If current is used when cooling another point shows itself. These points, however, are only detectable when a potentiometer is used to measure the voltage of the thermo-couple.

The maximum resistance of the rheostat is obtained as follows: Having decided that 500 watts will be the minimum required (see Fig. 3) at any time, and remembering that the most unfavorable condition for a minimum, i.e., the most favorable for a maximum, is when the furnace resistance equals the external resistance, we assume this condition and solve for the latter. Let R equal the resistance sought and assume the voltage as 110. Then

$$\frac{110}{2\text{ R}} = \text{Current flowing,}$$

and

$$\left(\frac{110}{2\text{ R}}\right)^2 \text{R} = 500 \text{ watts.}$$

Whence R = 6.05 ohms.

When using the maximum resistance of the rheostat (6 ohms), we find that 504 watts is the most that the furnace can possibly receive.

### Uses

The atmosphere of the furnace above 1200 degrees C. analyzes as follows: Oxygen, 0.20%; nitrogen, 68.90%; carbon dioxide, 0.70%, and carbon monoxide, 30.20%. If a different atmosphere is desired, gas may be admitted through a hole leading from the bottom of the furnace into the heating chamber. If an oxidizing atmosphere is desired all that is necessary is to leave the hole open and provide an opening at the top of the furnace and a strong current of air flows through the heating chamber.

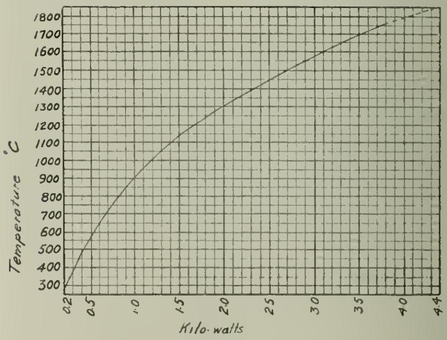

FIG. 3—KILOWATT-TEMPERATURE CURVE FOR GRAN-ANNULAR FURNACE

C. H. Fulton uses a gran-annular furnace, among other things, to make seger cone melting point determinations. The cones can be watched through a hole in the furnace cover, and good determinations be made at very high temperatures. His work with slags has already been mentioned.

F. A. Fahrenwald, doing research work for the National Dental Association, is using a gran-annular furnace. He uses it largely for melting metals, for the purpose of forming alloys, and the remarkable manner in which the furnace stands the severe usage deserves mention. It has been heated as many as twenty times in eight hours to a temperature of 1500 degrees C., the heating rate being so fast that that temperature was reached in less than fifteen minutes. In one instance the furnace was heated from room temperature to a white heat in eight minutes.

The writer is using one of the furnaces to find the critical points of alloys in a binary system. Some of the points are so slight that they cannot be detected unless the heating or cooling rates are very slow. By using the data given in Fig. 3 the thermal rate may be controlled as desired. For example, if the furnace is at a temperature of 1600 degrees C, and it is desired to locate accurately the position of critical points above 1400 degrees C., the wattage is set at 2300 and the cooling curve taken. The cooling takes about twenty minutes, while if the power is shut off the temperature drops to 1400 degrees C. in about one minute. If now the wattage be increased to 3100, a slow rate of heating will take place from 1400 up to 1600 degrees.

A temperature of 1800 degrees C. can be used with safety, as platinum has been melted in the furnace, in ounce lots, the Pt Pt-Rh couple having fused several minutes before the melt was removed. The maximum temperature of the walls of the heating chamber is limited to the fusing point of alundum (about 2050 degrees C.). It is hoped, however, that magnesia tubes will soon be available which will enable a temperature of about 2400 degrees C. to be reached.

Case School of Applied Science, Cleveland, Ohio.

# Concentration of Complex Sulphide Ore from the Mary Murphy Mine

BY DYKE V. KEEDY

The article under the above caption, in the January issue of METALLURGICAL AND CHEMICAL ENGINEERING, is very interesting. It occurred to the writer that it would be worth while to apply some figures to check it up. The results are rather surprising inasmuch as they vary so widely from those given as representing the recoveries effected by the preliminary jigging, tabling and vanning operations. One lot of 3989 tons was taken as a basis, assaying as follows:

| Gold | Silver | Lead | Zinc | Copper |
|---|---|---|---|---|
| 0.25 ozs. | 3.1 ozs. | 5.4% | 8.7% | 0.6% |

The recoveries are claimed to have been:

| Gold | Silver | Lead | Zinc | Copper |
|---|---|---|---|---|
| 75.9% | 50.6% | 86.7% | 58.6% | 55% |

From this lot of ore it is said there was obtained the following products assaying:

| | Wt., Tons | Gold, Ozs. | Silver, Ozs. | Lead, % | Zinc, % | Copper, % |
|---|---|---|---|---|---|---|
| Lead Concentrates...... | 138 | 2.26 | 12.4 | 48.8 | 10.8 | 0.7 |
| Zinc-Iron Middlings..... | 273 | 0.32 | 7.0 | 7.2 | 38.1 | 2.3 |
| Zinc Slime............. | 34 | 0.19 | 7.1 | 9.6 | 30.9 | 1.5 |
| Tailing............... | 3544 | 0.07 | 1.7 | 1.4 | 4.0 | 0.3 |
| | 3989 | | | | | |

On page 25 of the report it will be noted that the recoveries were calculated by deducting the metallic content of the tailings from that of the heads and counting the difference as recoveries made in the concentrating department; even so, the figures as given are slightly incorrect, the actual figures being:

| Heads, 3989 Tons Actually Contained | | Tailings, 3544 Tons Said to Contain | | Recoveries as by Difference | |
|---|---|---|---|---|---|
| Gold..... | 997.25 ozs. | Gold...... | 208.18 ozs | Gold ..... | 75.14% |
| Silver.. | 1236.59 ozs. | Silver..... | 602.48 ozs | Silver...... | 52.27% |
| Lead..... | 215.406 tons | Lead..... | 49.616 tons | Lead..... | 76.96% |
| Zinc..... | 347.013 tons | Zinc...... | 141.760 tons | Zinc . | 59.16% |
| Copper . | 23.934 tons | Copper.. . | 10.632 tons | Copper . | 55.57% |

These figures check pretty closely with those given in the report, except in the lead, but they should check exactly since they were presumably arrived at from the same starting point and by the same method of calculating.

This method of calculating recoveries is incorrect and misleading because of the very important fact that the large quantity of water used on the jiggs and tables and running to waste therefrom carries unseen and frequently unnoticed an unknown quantity of mineral values.

Rarely, if ever, are there any practical means at hand whereby this water can be caught and its burden of mineral values accurately determined, and since it is therefore practically impossible to catch and accurately sample the tailings, the only true and dependable method to pursue is from the other end of the operations, namely, counting, as being recovered, only the values carried in the concentrates and the balance as lost.

Figuring on this basis, we calculate the recoveries and distribute the percentage of the various values in the various products as per the following tables:

GOLD

TABLE "A"

SHOWING DISTRIBUTION OF VALUES

3989 tons of ore at 0.25 oz. =997.25 oz.

| | Tons | | Assay | Content | Per cent | |
|---|---|---|---|---|---|---|
| Lead Concentrates.... | 138 | tons at | 2.26 oz. | =311.88 oz. = | 31.27% | of tota |
| Zinc-Iron Middlings... | 273 | " " | 0.32 | " = 87.36 " = | 8.76% | " " " |
| Zinc Slimes.......... | 34 | " " | 0.19 | " = 6.46 " = | .65% | " " " |
| Amalgam............. | | | | =319.70 " = | 32.08% | " " " |
| Tailings ........... | 3544 | " " | 0.076 | " =271.85 " = | 27.24% | " " " |
| | 3989 | " " | 0.25 | " =997.25 " = | 100% | " " " |

Only the gold which reported itself in the amalgam and in the carpet, 32.08 per cent, and in the lead concentrate 31.27 per cent, total 63.55 per cent, can be dependably counted as saved. A portion, possibly 65 per cent or 70 per cent, of the gold carried in the zinc-iron middlings, 8.76 per cent, and in the zinc slime, 0.65 per cent, total 9.41 per cent, may also be saved, which would then bring the ultimate gold recovery up to about 70 per cent.

SILVER

TABLE "B"

SHOWING DISTRIBUTION OF VALUES

3989 tons of ore at 3.1 Oz. =12,365.9 Oz. Silver

| | Tons | | Assay | Content | Per cent | |
|---|---|---|---|---|---|---|
| Lead Concentrates.... | 138 | tons at | 12.4 oz. | = 1711.2 oz. = | 13.84% | of tot. silv |
| Zinc-Iron Middlings... | 273 | " " | 7.0 | " = 1911.0 " = | 15.45% | " " " |
| Zinc Slimes.......... | 34 | " " | 7.1 | " = 241.4 " = | 1.95% | " " " |
| Tailings............. | 3544 | " " | 2.4 | " = 8502.3 " = | 68.76% | " " " |
| | 3989 | " " | 3.1 | " =12365.9 " = | 100% | " " " |

On the assumption that the waste waters from the jiggs, tables and vanners did not carry away any values whatever, which, of course, is not true, and provided the sampling and assaying of the tailings truly represented actual facts, then the tailings would have carried only 1.7 ozs. per ton or 48.71 per cent of the total silver. But by these calculations we find the tailings, including the losses in the wash water, actually carried 2.4 ozs., or 68,76 per cent of the total silver; less that which was caught on the amalgam plates and carpets. No weights having been given in the report respecting the quantity of silver thus recovered, makes it impossible to calculate the ultimate recovery.

LEAD

TABLE "C"

SHOWING DISTRIBUTION OF VALUES

3989 tons of ore at 5.4% =215.406 tons lead

| | Tons | | Assay | Content | Per cent | |
|---|---|---|---|---|---|---|
| Lead Concentrates.. | 138 | tons at | 48.8% | = 67.344 tons = | 31.26% | of tot. lead |
| Zinc-Iron Middlings. | 273 | " " | 7.2% | = 19.656 " = | 9.13% | " " " |
| Zinc Slime ..... | 34 | " " | 9.6% | = 3.264 " = | 1.51% | " " " |
| Tailings ...... | 3544 | " " | 3.53% | =1251.42 " = | 58.10% | " " " |
| | 3989 | " " | 5.4% | =215.406 " = | 100% | " " " |

These calculations are made from the heads and the three weighed and sampled products, only one of which, however, at this stage of the operations, is marketable; the other two are to be further treated. The sampling of the tailings, as given in the report, 1.4 per cent, is fairly to be questioned, for reasons before stated. The lead not reporting in the lead concentrates, or in products yet to be treated, must be counted as lost. It is shown that 58.10 per cent of the total lead had passed into the tailings and was lost at this stage of the operations, leaving 41.90 as a possible ultimate recovery, even if supposing that a perfect separation of the lead will be made from the zinc-iron middlings and zinc slimes. We cannot find any way to justify the claim, made in the report, of a recovery of 86.7 per cent, but rather it looks as if some figure between 35 per cent and 40 per cent would be the maximum.

### ZINC

TABLE "D"

Showing Distribution of Values

3989 tons of ore at 8.7% =347.043 tons of zinc

| | | | | | |
|---|---|---|---|---|---|
| Lead Concentrates.. | 138 | tons at 10.8% | = 14.904 tons | = 4.29% | total zinc |
| Zinc-Iron Middlings. | 273 | " " 38.1% | =104.013 " | = 29.97% | " " |
| Zinc Slimes........ | 34 | " " 30.9% | = 10.506 " | = 3.04% | " " |
| Tailings.......... | 3544 | " " 6.14% | =217.620 " | = 62.70% | " " |
| | 3989 | " " 8.7% | =347.043 " | =100% | " " |

In like manner as with the lead, these calculations are made from the heads and the three weighed and sampled products, the tailings being calculated by difference; this for the reasons as stated before. It would be obviously unfair and misleading to make calculations upon recoveries that clearly were not made. The zinc reporting in the lead concentrates is worse than lost, as its presence in that product induces a penalty. Inasmuch as 62.70 per cent of the zinc is lost in the tailings and 4.29 per cent in the lead concentrates, a total of 66.99, there remains only 33.01 per cent from which the ultimate recovery must be made by the slime tables and electrostatic machines. It looks as if the ultimate recovery will be even below 20 per cent. In any event it seems quite impossible to check up or account for the 58.6 per cent recovery as claimed in the report.

### COPPER

TABLE "E"

Showing Distribution of Values

3989 tons of ore at 0.6% =23.934 tons of copper

| | | | | | |
|---|---|---|---|---|---|
| Lead Concentrates.. | 138 | tons at 0.7% | = .966 tons | = 4.04% | total copper |
| Zinc-Iron Middlings. | 273 | " "2.3% | = 6.279 " | = 26.23% | " " |
| Zinc Slime. ....... | 34 | " "1.5% | = .510 " | = 2.13% | " " |
| Tailings.......... | 3544 | " "0.47% | =16.179 " | = 67.60% | " " |
| | 3989 | " "0.6% | =23.934 " | =100% | |

These calculations are made on the same basis as before and, of course, for the same reasons. Technically, it may be claimed that there is here shown a recovery of 32.40 per cent, inasmuch as this amount of copper reported in the so-called finished products of this department, but commercially the story is different, since the copper tenor of the lead concentrates is too low to fetch any payment therefor. The finished copper-iron products from the electrostatic machines do not run very high in copper, if on dry assay. The high tenor of zinc will induce a penalty. Were it not for the values in gold and silver these products would hardly pay to ship. At present market prices they will fetch about $20 per ton. At best there remains less than 30 per cent of the total copper, reporting in the products, subject to retreatment, from which any marketable copper product can be recovered. Upon what basis, therefore, can be made the claim of a 55 per cent recovery?

As a summary of the foregoing tables and making a comparison with the claims made in the report, wherein the Tailings are figured against the Heads and in the other case, wherein the Concentrates are figured against the Heads, we have the following:

| According to the Report | Tailings Figured Against Heads | As Herein Calculated | Concentrates Figured Against Heads |
|---|---|---|---|
| Gold Recovered | 75.9% | Gold Recovered | 72.76% |
| Silver " | 50.6% | Silver " | 31.21% |
| Lead " | 86.7% | Lead " | 41.90% |
| Zinc " | 58.6% | Zinc " | 37.30% |
| Copper " | 55.0% | Copper " | 32.40% |

We will bear in mind that these figures relate only to recoveries as meaning that we have only deducted, as losses, the values lost in the tailings. There are losses already suffered even at this stage of the operations which are just as decided losses, in fact, as those passing away in the tails, such as the Zinc reporting in the Lead Concentrates, etc. In the subsequent steps in the operations, that is, retreatment of the Zinc-Iron Middlings and Zinc slimes further losses will be suffered. The above figures representing silver recoveries will have to be modified to some extent on account of the unknown quantity of silver caught on the carpet.

### ELECTRO STATIC DEPARTMENT

Had there been given any figures with respect to the weights of the products resulting from the electrostatic machines, it would be interesting to digest them to ascertain what recoveries were made. The question naturally arises as to why they were omitted as their absence is all the more noticeable since the weights were so freely given in the grinding and rough concentrating departments. The assay figures are interesting, particularly those relating to the "Retreatment of Electro Static Middlings."

For reasons given later herein, we are justified in assuming the chemist's figures to be correct and now we are prompted to ask, from whence comes all this Gold and Silver? In the table referred to, page 26, we find a Feed said to carry .52 oz. Gold and 9.1 ozs. Silver; this is presumably split into two products, viz.: Zinc product and Iron product; one carrying .56 oz. Gold and 9.8 ozs. Silver and the other .62 oz. Gold and 9.9 ozs. Silver. It might be assumed that a certain amount of a Middlings product, could also have been made, running very low in Gold and Silver and which would account for these values being so high in the other two products, but it appears from the assay figures that but little disturbance was made with the remaining chief constituents of the feed. For instance, the Lead tenor of the feed was 8.8 per cent; that of the Zinc product 11.9 per cent and that of the Iron product 8.7 per cent. It seems therefore after careful study of the assay figures, given in this table quite impossible to account for the large increase in Gold and Silver by reason of any Middlings product also being made. It looks very much as if some one has been fooling himself, unintentionally perhaps, but fooling himself just the same.

It does not seem possible that the results as shown by the tables given in the report are the very best attainable by the electrostatic machines. These fall so very far short of those that have been obtained in the treatment of similar ores that it seems more than likely that very material improvements can and will be made as soon as the machines are properly adjusted and the operatives get better acquainted with the requirements and learn how to meet them.

If and when certain obvious improvements have been made in the crushing and grinding departments (herein later discussed), an increased quantity of feed will come to the statics and in better condition for treatment. There will also be produced a less quantity of the extremely fine grades which are more difficult for the statics to handle satisfactorily. Hence in the final results a very marked improvement will be shown.

### REGRINDING OF STATIC MIDDLINGS

In the absence of any figures respecting relative weights and having only the assays given, it is impossible for one to see any good net results coming from the operation of this "Retreatment of the Static Middlings," but on the contrary, it looks more as if the operations resulted in a net loss. The Lead seems to have tended to concentrate in the Zinc product, which of course results in a loss. The tenor of Zinc in the Zinc product was brought up only about 6.6 per cent or say from 28.2 per cent to 34.8 per cent while the Lead in this product increased from 10.2 per cent to 11.1 per cent also there was an alleged increase in the Gold and Silver. A marketable Copper-Iron product was made although it yet carried 16.4 per cent Zinc which would largely offset its copper values were it not for the values in Gold and Silver which it is alleged to contain. The net results are unknown and as yet questionable.

### MONNELL SLIMER

It seems hardly worth while to comment upon the results as shown, from the Monnell Slimer,—except to raise the question as to the purpose to be served by keeping it at work. We realize that it has set for it, by reason of the character of feed, a task that would be very difficult for any machine to perform with any degree of satisfaction. The results in this department will show marked improvements when proper changes have been made in the Grinding Department and yet greater improvements when the whole slime problem is approached from an entirely different angle.

### REGRINDING APPARATUS

The figures given on page 24, respecting the work done by the Hardinge Mills and the Tube Mill are very interesting but their value is much enhanced when they are put in the form of percentages. The assay values of the various screen products being given, it is possible to calculate the assay of the original feed as well as that of the discharge, as a check upon the former as well as a cross check upon the chemist's work and a check also upon the one who weighed the various screen products. These figures also enable us to calculate the distribution of the values carried in the screen products, which is very important.

The way these figures check up is worthy of some comment; considering the fact that the figures representing the assay values of the Feed and Discharge were obtained by roundabout calculations which involved possible errors in taking the weights of the various screen products as well as possible errors in the chemist's figures, and concurrently bearing in mind that small errors, at the start, increase rapidly as the calculations proceed. It must be noted that the final figures check up very closely. This indicates an uncommon degree of accuracy in the chemist's figures and warrants confidence being placed in them.

The figures given in the report respecting the assays and weights of the various screen products resulting from the screen analyses of the various feeds and discharges to and from the Hardinge mills are herein tabulated in the form of percentages by weight and so as to clearly reveal the distribution of values in all the various screen products, as follows:

TABLE I

There appears nowhere in the report any information respecting the degree of fineness to which the ore must be crushed in order to free the greater part of the various mineral values. This knowledge is of the utmost importance to one who has in hand the task of recovering values in any ore and particularly one like this under discussion. One may find some warrant in assuming that this ore is being, in the very first stages, too finely ground, from the fact that the statement is made that a certain amount of tailings is rejected from the table treating the coarsest grade of minus 1 mm feed. We may therefore for the moment assume that ore 0.0122 in., is fine enough to free such a large percentage of the minerals as to produce, in the concentrating department, not too great a proportion of middlings. On this assumption let us see what has been done in the grinding mills; taking each one of the four tables of figures separately and finding the percentage, by weight, of the material that is coarser than 60 and comparing it with that which is finer and concurrently comparing distribution of values; thus, in this manner, finding out how much unnecessary and really undesirable and actually harmful work is being done in the grinding mills. Any quantity of ore being ground beyond the degree of fineness necessary to free the respective minerals is decidedly harmful, always.

It will be seen at once that in every instance much of the feed going to the grinding mills is already fine enough; this being true, why should it be further punished by passing through the slaughter house? In detail we see in the Feed in Table I A 23.42 per cent minus 60 mesh; in Table II B 21.35 per cent; in Table III C 18.71 per cent and in Table IV D 34.14 per cent. The immediate effect of passing this fine material through the mills is to largely increase the already too high percentage of slimes. In practice it might be found desirable to classify at as coarse a grade as 50 mesh; say 0.0146 in. instead of 60 mesh 0.0122 in., or at some point in between, or it may be found that even a coarser grade would be desirable.

The work done, as represented by Table I A is particularly bad, inasmuch as the 23.42 per cent by weight, of the FEED carries, in the minus 60 mesh grade, 46.94 per cent of the total Lead content; while in the DISCHARGE we find, in the same grade, 67.23 per cent by weight, carrying 86.65 per cent of the total Lead content; and of this 86.65 per cent of Lead 48.62 per cent has already been crushed to pass a 200 mesh screen; much of this, no doubt, is almost as fine as pigment and on this account it is extremely difficult, if not impossible to recover its Lead and other values. All the other tables could be discussed in the same manner and the same general conditions found to exist.

We have no information with respect to the relative tonnage of feed going to the pebble mills, respectively, for then it would be well worth while to ascertain, definitely, what percentage of the total values in the ore is ground finer than 200 mesh. But since the percentages, by weight, of all the screen products passing to and from the machines and their assay values have been thrown into percentage tables to show the distribution of values, it might be well to note the following:

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Table | I. | Minus | 200, | carries | 48.62% | Total Lead and | 30.47% | Total Zinc |
| " | II. | " | 200, | " | 56.86% | " " " | 39.28% | " " |
| " | III. | " | 200, | " | 42.26% | " " " | 21.30% | " " |
| " | IV. | " | 200, | " | 49.31% | " " " | 50.16% | " " |

It will be readily seen by reference to the tables that fully 1/3 of the minus 200 mesh, reporting in the DISCHARGE was not made in the pebble mills, but was passed in as feed when it was already fine enough to pass a 200 mesh screen. It is fair to assume that this minus 200 mesh feed which passed into the machine was therein ground still finer. It appears therefore that so far as this part of the work is concerned, the practice carried on in the grinding department would be much better suited for a paint works than for a concentrating mill.

This digest of the work, done in the grinding department, clearly indicates that not far from 50 per cent of all the Lead carried in the jigg tailings and middlings was ground fine enough to pass a 200 mesh screen and much of this 50 per cent was ground to a degree of fineness closely approaching that of pigment. This in itself goes a long way to show the reason why there was made, in the operations, such low percentages of final recovery.

If and when necessary changes and adjustments have been made looking towards a radical reduction of the percentage of fines and slime produced, and when a minimum has been reached, there is no reason why a satisfactory recovery of their contained values cannot be made, provided they are carefully and properly classified and passed over a good slime table.

In this connection it may be said that last summer while making some tests for the purpose of deciding upon the best way to treat fines and slimes of this character and to make a selection of the best slime table to use for the purpose, we had a quantity of "tankage" carrying values in Zinc and Lead, all of which was fine enough to pass a 200 mesh screen. This was passed through an improved classifier, which had then lately been designed and put on the market. The objective point was to wash away nothing but the true slime or colloidal matter, which was sent to waste as being unamenable to further mechanical treatment. From the oversize, or underflow, there was made a Lead product, carrying 77 per cent Lead, every bit of which would pass a DuFour silk cloth screen of 275 mesh; and a Zinc product carrying 51 per cent Zinc. This is only mentioned to show what can be done with a minus 200 mesh product, only provided it has not previously been pulverized to actual slime, and provided it is properly classified, and a suitable slime table used to further treat it.

On Page 23, of the report, there appears a remark to the effect that "while the work of the Hardinge Mills is satisfactory with respect to grinding Tailings, they have not done so well in the work of grinding Middlings, on account of producing too much mineral slime." There is very substantial ground upon which to base a belief that the fault has not been so much with the Hardinge Mill itself, as with the way these machines have been handled and the character of the feed passing to them. Refer for instance to

TABLE No. 4; Four foot Hardinge Mill, grinding Jigg Middlings. Observe that 34.14 per cent, by weight, of the FEED was already finer than 60 mesh; and 10.97 per cent was minus 200 mesh; while in the DISCHARGE 97.56 per cent was finer than 70 mesh and 51.22 per cent was finer than 200. This 34.14 per cent, by weight, of the FEED, finer than 60 mesh, should probably have bypassed the Hardinge, and certainly so, provided the greater part of it consisted of free mineral particles; but at any rate, the 10.97 per cent by weight, which was finer than 200 mesh, should have bypassed. The remaining 65.86 per cent (plus 60 mesh) or at most, the 74.40 per cent (plus 100 mesh) should have been passed through the Hardinge rapidly, in the effort to grind it only fine enough to pass a 60 or a 100 mesh screen, as the case might be, but surely not to so severely pulverize it. The oversize to be returned to the Hardinge, after classification.

It must be borne in mind that the efficiency of Rolls falls away alarmingly when they are put to the work of such fine grinding as is necessary in this case. The wisdom of making the proposed change from Hardinge Mills to Rolls is therefore very much to be questioned.

There are several well known ways to regulate the performances of the Hardinge Mills, so as to make the results conform pretty fairly well with current requirements.

In treating an ore like the one under discussion, and in which the mineral constituents are very friable and strongly tend to break down into slimes, grinding operations should be carried on with these features and conditions kept well in mind. It certainly is necessary to classify the feed, so as to deliver to the mill no material that has already been ground fine enough to physically free the mineral particles. It is equally necessary to classify the discharge and to return the oversize. When this practice is carried on and when proper adjustments have been made, it will be found that there will be a very marked decrease in the quantity of true slimes that is produced.

After a careful study of the report, as published, and the digest of the same as given herein, we believe it will be seen that by making some changes in the grinding department looking towards a system of step grinding for the purpose of effecting a gradual fine granulation of the ore particles, as opposed to a too sudden and violent pulverization, a great improvement can be made over the indifferent recoveries that it will be seen are now being effected. To the proposed changes to be made in the Grinding Department there could also, to good advantage, be added a certain number of classifiers, located at various points in the system to enable the ore to bypass the grinding department as soon as it has reached the degree of fineness necessary to free the mineral particles; letting the jigg and table work be such, as to pass for regrinding, substantially, only such middlings as are true Middlings (attached particles) and to inaugurate a better system of treating the fines and slimes after they have been radically reduced in quantity.

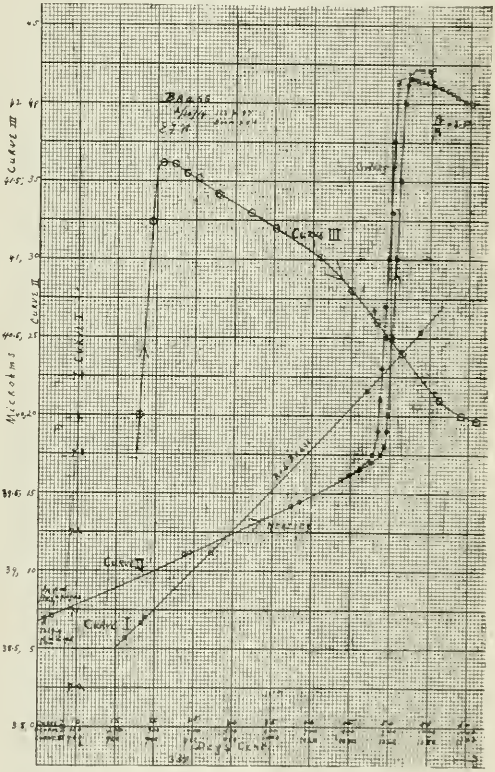
**A submarine oxyhydrogen torch** is reported to have been tested in Kiel harbor, Germany, for the purpose of testing the possibility of dismantling sunken vessels. A 4-inch iron case was cut in half a minute.

## Resistivity of Brass; Solid and Molten

BY EDWIN F. NORTHRUP

It has been pointed out to the writer that, in designing certain types of electric furnaces for the treatment of molten brass, an accurate knowledge of the electrical resistivity of this alloy in the molten state would be useful. As both the method and equipment for making this determination were available, the writer decided to measure in both the solid and liquid state the resistivity of ordinary rod brass and publish the data for the benefit of any one who might find it useful.

Alloys, which pass under the name of brass, are of very variable composition and a complete specification of the particular alloy for which data were obtained would require the making of an accurate chemical analysis. This the writer did not feel justified in undertaking.[1] The brass used in the measurement was the ordinary rod brass, in rods about 0.3 cm in diameter, commonly used in the machine shop. Its quality is, to a certain extent, determined by a knowledge of its density. The density of the rod brass was, therefore, determined by a measurement of the mass and the volume of a rod about 91 cm long, and found to equal 8.472. Its specific resistance while in the form of a rod was also determined with precision in the temperature range 16.25° C. to 53.70° C. Curve I and the table record the results obtained. With this much exact



RESISTIVITY CURVES

---

[1] After this article had been put into print, an analysis was made by courtesies of the Ajax Metal Company, with the knowledge and consent of Dr. Northrup, of pieces of the same lot of brass used in his determinations, and it was found to contain 63% copper, 34.58% zinc, 2.42% lead, and traces of tin and iron.—Carl Hering.

information, respecting the nature of the brass used in the measurements, it is thought that the data obtained apply to a material of sufficiently definite composition to meet engineering requirements, and to serve the designer with information sufficiently precise for his purposes.

The method of measurement employed for measuring the resistivity of the brass from a temperature at which it was molten down to room temperature, and again from room temperature up to 1104° C., was in all essential respects the same as that employed by the writer in measuring the "Resistivity of Copper in Temperature Range 20° C. to 1450° C." published in the *Journal* of the Franklin Institute, January, 1914. The furnace employed in measuring brass and all other materials to a temperature of 1600° C. or more has already been described in METALLURGICAL AND CHEMICAL ENGINEERING, January, 1914.

Considerable precaution must be exercised in measuring an alloy like brass, one of the constituents of which has a low vaporization temperature. Thus the vaporization temperature of zinc is given as 918° C. If the brass is raised, therefore, to a temperature at which the zinc volatilizes, not only is the composition of the brass altered in the course of the measurement, but the measurement is interfered with by the vapor of zinc (which being in a CO atmosphere does not oxidize) congealing on the under surface of the furnace cover, thus short-circuiting the molybdenum wire terminals employed.

The first time the measurement was attempted these results were not foreseen and the furnace was brought to a temperature of a little over 1200° C. before the container was filled with brass. The result was that a goodly proportion of the zinc distilled out of the brass and deposited a thick layer of metallic beads on the lower surface of the furnace cover. Fortunately the construction of the furnace is such that no injury happened to the furnace.

After this experience the container was heated before filling with brass to a temperature of only 1020° C., and immediately allowed to cool, readings of temperature and resistivity being taken as the cooling proceeded (see curve II). After the container had cooled to 19.4° C. the resistivity was measured again with rising temperature and the temperature was carried this time to 1104° C. (See curves II and III). The agreement at 972° C. between the cooling and the heating curves, at which temperature the brass is molten, was exact. At 940° C. the difference between heating and cooling resistivity is 0.42 per cent.

After the measurement was over it was found that a very small amount of zinc had distilled out of the brass, the maximum temperature reached being, as above stated, 1104° C. Since pure zinc is said to vaporize at 918° C. it follows that when zinc is alloyed with copper the vaporization of zinc occurs at a higher temperature. The vaporization appears to be inappreciable until a temperature of nearly 1090° C. is reached. Since the resistivity is very sensitive to changes in the composition of the material, and since the writer has now so perfected the method of measuring the resistivity of a molten metal or alloy that the error need not exceed 0.1 of one per cent, determinations of resistivity might be employed with advantage for determining alterations in composition of alloys due to vaporization or other causes.

Referring now to the curves we invite attention to the following points: The resistivity of the rod brass is 7.101 microhms per centimeter cube at 20° C. and 7.550 microhms at 50° C. This gives as the coefficient of rod brass, reckoning from 20° C., 0.0021. Thus brass increases in resistance with raise of temperature about one-half as fast as copper in the solid state. The increase is not quite linear, curve I being very slightly convex toward the temperature axis.

The resistivity of the brass which had been cooled from the molten state in the container measured 6.957 microhms at 20° C. It was probably somewhat less than this, because the brass in cooling in the container from the molten state must suffer some shrinkage and the measurement gives the volume and not the mass resistivity of the brass. We conclude, therefore, that the resistivity of brass which has been slowly cooled from the molten state is at least 2 per cent less at 20° C. than the resistivity of the same brass when drawn into a rod. The ratio of the resistivity of the brass just after fusion is complete, to the resistivity just before fusion starts, is 2.37+. This is a very large increase in resistivity in passing from the solid to the molten state and is about 18 per cent greater than in the case of many of the pure metals.

The change in the resistivity with increase in temperature in the molten state is plotted on an enlarged scale in curve III. It is interesting to note that the resistivity *decreases* with increase in temperature. The writer has shown in a joint article by E. F. Northrup and V. A. Suydam, *Journal* of the Franklin Institute, February, 1913, that zinc has a strongly negative temperature coefficient in the molten state up to a temperature of 750° C. This constituent of the brass apparently determines the slope of the curve in the molten state. The fact that curve III begins to show an inflection at about 1090° C., the decrease in the resistivity becoming less rapid, indicates that it is at about this temperature that the brass begins to lose some of its zinc by vaporization. If all the zinc were to vaporize out the curve would become like that for copper, which shows a strongly positive coefficient at all temperatures up to the highest measured, which was 1450° C.

TABLE I.

| Temp. Degs. C. | Microhms per cm cube | Ratio of resistivity at two temps. | Notes |
|---|---|---|---|
| 20... | 7.101.... | $\frac{\rho_{1000}}{\rho_{20}} = 5.922$ | Rod brass<br>Density = 8.472 |
| 20... | 6.957.... | $\frac{\rho \text{ liquid}}{\rho \text{ solid}} = 2.37+$ | Cooled slowly from molten state |
| 50... | 7.55 | ........................ | Rod brass |
| 944... | 41.61 | ........................ | Heated slowly from solid state |
| 1000... | 41.20 | ........................ | Heated slowly from solid state |
| 1084... | 40.11 | ........................ | Heated slowly from solid state |

The writer in measuring the resistivity of the pure metals confirmed all his results by making each measurement twice, each time in a different container. The above measurements on brass were only made once, as the variable composition of this material is such that there would be no justification for the expenditure of a large amount of time to obtain very high accuracies. However, the writer believes that the data given in curve I may be relied upon to within 0.2 of one per cent and that in curve III to within 0.5 of one per cent.

The examination of the resistivity curves of the alloys is now, certainly, a matter of routine, if one is provided with a suitable equipment, and the writer believes that these curves would give very considerable information to metallurgists respecting the properties and the behavior of alloys. He hopes to see, in the near future, many measurements of the above character made and published.

Palmer Physical Laboratory, Princeton, N. J

**The Chirese iron and steel trade** has been upset by revolutionary disturbances during the past two years. Both imports and exports of iron and steel products fell off remarkably in 1912 as compared with 1911, and the 1913 business has not returned to normal. A new 300-ton blast furnace is in course of construction at Hanyang, and another at Tayeh.

# Industrial Synthetic Production of Sodium Cyanide*

BY CAMILLE MATIGNON

Among the nitrogen compounds nitric acid, ammonia, and cyanide, the last one is only of secondary or minor industrial importance as compared with the other two. Chile supplies the world annually with 2,500,000 tons of sodium nitrate; the manufacture of gas and coke for metallurgical purposes furnishes the market with 1,000,000 tons of ammonium sulphate; the cyanide industry, on the other hand, is limited annually to from 20,000 tons to 25,000 tons of cyanide compounds, in the form of sodium and potassium cyanide, ferrous and ferric cyanide and Prussian blue.

The use of cyanides has increased particularly since the introduction of the Arthur and Forrest process of gold extraction in the year 1888. Before that time the annual production of cyanide of potassium, which was the only alkali cyanide then in use, did not exceed 100 tons; it reached 450 tons in 1888; from then on it increased annually by about 1000 tons of potassium cyanide and sodium cyanide, the latter having been introduced into the market in the meantime. Almost the whole quantity of alkali cyanides is used for the gold extraction process; the gold and silver plating industry consume only an inconsiderable amount of cyanides.

As said before, the cyanide compounds are only of secondary importance as to quantity in the industry of nitrogen compounds. On the other hand, as to price the nitrogen of the cyanide is much more valuable than nitrate nitrogen or ammonia nitrogen. The value of these latter two does not exceed 13.6 cents per pound, while the price of cyanide nitrogen reaches and exceeds 54 cents per pound. Under such conditions it should be worth while to convert nitric acid or ammonia into cyanide.

There are several reactions by which these transformations can be achieved. None of them has been made use of practically for transforming sodium nitrate into sodium cyanide, while ammonia is actually used for the manufacture of cyanides. The inverse reaction is much more easily carried out; cyanide produces easily ammonia when heated in a current of steam. Hydrocyanic acid, which is the nitrite of formic acid, has a tendency to decompose into ammonia and formic acid, and the salts of hydrocyanic acid give ammonia and formates. The formates are decomposed at red heat and only alkali carbonate remains when sodium cyanide is heated. $2\,CN\,Na + 4\,H_2O = 2\,NH_3 + Na_2CO_3 + CO + H$.

A great number of research chemists are occupied at the present time with the industrial problem of the synthesis of ammonia by way of the cyanides. This seems to me to be illogical, for hydrocyanic acid is a substance which when produced from its elements absorbs heat:

$$C + N + H = CNH - 30.5 \text{ cal.}$$

and it will always be more expensive than ammonia, the heat of formation of which is exothermic:

$$N + 3\,H = NH_3 + 12 \text{ cal}$$

The electrolytic production of sodium with melted sodium hydroxide as electrolyte has put us into a position to produce sodium very cheaply. Starting from sodium and from ammonia, a process has been elaborated which supplies the metallurgy of gold with a considerable amount of the cyanide it needs.

The English factory of Castner is intimately connected with the history of sodium and there the preparation of sodium, and subsequently that of cyanide, was first studied; but only with the improvements introduced by the Deutsche Gold und Silberscheide Anstalt of Frankfurt did the manufacture of cyanide become an industrial process.

On examining the formula of sodium cyanide CN Na (N = 14 and Na = 23) it will be seen that 1 lb. of cyanide nitrogen requires 1 lb. of ammonia nitrogen and about 2 lbs. of sodium. Taking 13.6 cents as the price of 1 lb. of ammonia nitrogen, and 54.4 cents as the value of 1 lb. of cyanide nitrogen, there remains a difference of 40.8 cents to cover the cost of 2 lbs. of sodium plus the cost of transformation and profit. As the electrolytic process of Castner with cheap electric power can produce 1 lb. of sodium at 9.05 cents or 18.1 cents for 2 lbs. there remains finally a margin of 22.7 cents to cover the cost of manufacture and profit.

## I. Original Castner Process

### 1. THE PRINCIPLE OF THE PROCESS.

Ammonia gas is absorbed by sodium at 400° C. with the formation of amid and the liberation of hydrogen.

$$NH_3 + Na = NH_2Na + H$$

This amid, when melted with one molecule of sodium cyanide is converted into sodium cyanamide between 550° and 600°.

$$NH_2Na + CN\,Na = CN_2Na_2 + H_2$$

Finally, this cyanamide, intimately mixed with carbon, fixes the latter at 750° to 800° with the formation of cyanide.

$$CN_2Na_2 + C = 2CNNa.$$

The molecule of cyanide which has served as intermediary, is thus recovered.

By proceeding in a different manner, the use of this intermediary molecule of cyanide can be avoided. A first carbon atom converts two molecules of amid into sodium cyanamide.

$$2NH_2Na + C = CN_2Na_2 + 2H_2.$$

Further on at 800° a second atom of carbon produces cyanide.

$$CN_2Na_2 + C = 2CNNa.$$

Castner's first idea was to produce cyanide from elementary nitrogen. When looking at the equation

$$2C + 2Na + N_2 = 2CNNa + 50 \text{ cal},$$

we find only one gaseous substance, the other two being solid or liquid; the enormous quantity of 50 cal for one gaseous molecule leaves no doubt of the possibility of the reaction. This, in fact, I had proved before I knew of Castner's experiments.

A current of pure nitrogen passing over a mixture of carbon and sodium has given me cyanide, although the yield in two or three preliminary trials has not been high. Castner had already made similar experiments in 1894. He poured molten sodium slowly over carbon heated in a vertical cylinder, while a current of nitrogen entered the cylinder sideways. The cyanide formed ran off at the bottom. The yield of cyanide was thus greater than by sending the nitrogen into the mixture of carbon and sodium. Castner soon found, however, that it was better to replace the elementary nitrogen by ammonia gas.

In the first period of the manufacture of cyanide, Castner operated successively in two apparatuses. The first one served for the production of sodium amid at 300-400°, the second one converted the amid into cyanide at 700-800°.

### 2. PREPARATION OF SODIUM AMID

Sodium is acted upon by ammonia in a horizontal rectangular retort A, the bottom of which is slanting, in order to facilitate the movement of the products (see Fig. 1). That part of the retort above the liquid metal M is divided into compartments by means of

---

*From *Revue Generale des Sciences*, Vol. 24, pp. 882-86 (1913), translated by Alex F. Fuerst.

vertical partitions C which touch the metallic bath; each of these partitions is fixed ultimately to opposite sides of the retort, as shown in Fig. 2, in order to force the ammonia gas to circulate from one compartment to the other and thus to remain as long as possible in contact with the sodium.

To operate the apparatus, the retort is heated to 300-400° C.; well dried ammonia gas is then sent through the retort in order to replace the air contained in it. The apparatus is then filled through funnel D with melted sodium until it overflows at G and tends to run away through the siphon J; the ammonia gas which is continually introduced through N is gradually absorbed on the surface of the sodium.

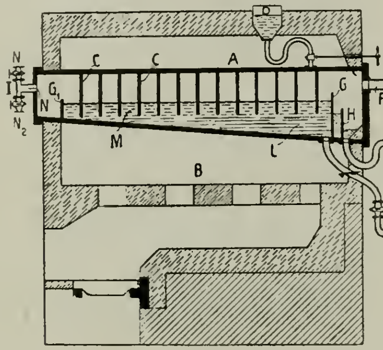

FIG. 1—VERTICAL CUT THROUGH APPARATUS FOR THE MANUFACTURE OF SODIUM AMID

A, Horizontal Retort; B, Furnace Room; C, Vertical Partitions; M, Liquid Metal; D, Funnel for the Introduction of Melted Sodium; N, Entry for Ammonia Gas; Exit for Hydrogen Gas; T, Siphon; E, K, $N_1$ and $N_2$, stop cocks.

The sodium amid which forms is also liquid and as it is heavier than sodium it tends to sink to the bottom of the metallic bath, leaving always pure sodium exposed to the ammonia. The amid passes through a small opening in the partition G into M and can be withdrawn through the siphon J. The ammonia gas is absorbed in theoretical amounts. The hydrogen escapes through F. The amid has become of considerable importance lately as it is required in the synthetic production of indigo from phenylglycine.

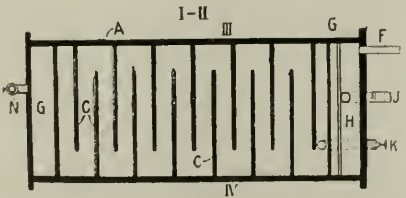

FIG. 2—PLAN OF APPARATUS ALONG I II

### 3. MANUFACTURE OF THE CYANIDE

The conversion into cyanide takes place in a cylindrical vertical retort A (Fig. 3) with a conical bottom. The retort is filled with wood charcoal through the funnel C, and heated to 800° C.; melted sodium amid is then gradually introduced; hydrogen escapes through F while molten cyanide runs off through the siphon E into molds where it solidifies.

### II. Castner-Roessler Process

Roessler, of the Deutsche Gold und Silberscheide Anstalt of Frankfurt, found that the yield in the second operation could be considerably improved. He found it to be the resultant of two consecutive reactions. At the temperature required for the conversion into cyanide, the sodium amid already undergoes decomposition with liberation of nitrogen and the yield is that much less. Moreover, some sodium cyanamide is found to be present in the cyanide; and the quantity of the cyanamide increases with the lowering of temperature. Thus when sufficient heat is applied some of the amid is decomposed and if the heat applied is not sufficient an increasing amount of cyanamide instead of cyanide is formed.

After much study, Roessler succeeded in obtaining an almost quantitative conversion of ammonia into cyanide by conducting the whole operation in three phases. Formation of amid, transformation into cyanamide, and conversion into cyanide. The second operation takes place at the low temperature of 300-400°, and consequently under conditions in which the amid is stable; further the cyanamide is not decomposed at 800° C., the temperature which is required for conversion into cyanide.

As we have already shown, the conversion of amid into cyanamide may be carried out in two different ways; either by melting the amid together with an equivalent amount of cyanide:

$$NH_2Na + CNNa = CN_2Na_2 + 2H_2,$$

or by heating the amid at 350-400° with charcoal,

$$NH_2Na + C = CN_2Na_2 + 2H_2.$$

This latter is one of the most remarkable reactions since hydrogen is replaced by carbon.

This operation is carried out as follows: The amid is melted with very finely divided carbon; as soon as a temperature of 380° C. is reached a violent development of hydrogen takes place; at the same time the whole mass loses its fluidity while the reaction proceeds, because the melting point of ordinary cyanamide lies at 550° C. For the completion of the reaction it is, therefore, necessary to raise the temperature gradually to 550 or 600°. Under these conditions the yield of cyanamide is quantitative.

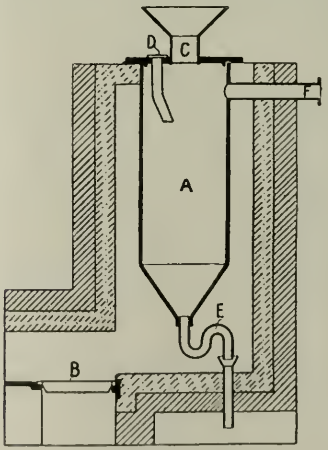

FIG. 3—CASTNER'S APPARATUS FOR CONVERTING SODIUM AMID INTO CYANIDE

A, Retort; B, Furnace Room; C, Funnel for the Introduction of Wood Charcoal; D, Opening for the Introduction of Melted Sodium Amid; E, Syphon for the Removal of the Cyanid.

The need of very finely divided carbon is self-evident, since each molecule of amid must find the required amount of carbon for its conversion. The replacement of carbon by liquid or gaseous hydrocarbons has been proposed and the same result is thereby much more easily achieved; acetylene particularly allows of a very rapid reaction, but its use increases the cost.

The process is carried out as follows by the Deutsche Gold und Silberscheide Anstalt and by those companies which are its licensees.

The various phases of the operation are carried out successively in one apparatus, which consists of a number of large iron crucibles. Each crucible is charged with 70 kilograms (about 156 lbs.) of finely divided wood charcoal. Ammonia is passed slowly over the crucible at 500° in order to replace the air; then the current of gas is increased, and 100 kilograms (223 lbs.) of sodium are added. The temperature is slowly raised to 600° C., which is the temperature required for conversion into cyanamide. Under these conditions, neither ammonia nor amid is decomposed. For the conversion into cyanide the temperature is finally raised 800° C. All that is necessary immediately to obtain a commercial product without any further treatment is to let the melted cyanide run into molds. The yield is quantitative, no losses are experienced except those inherent in every manufacturing operation. All that is required is a rigid control of temperatures. The cyanide thus prepared contains 90 to 98 per cent pure cyanide and is equivalent to 120 to 130 per cent of cyanide of potassium, which is the current method of valuation of cyanide.

The Castner process, with these improvements, is used by the Deutsche Gold und Silberscheide Anstalt in their works near Frankfurt; also by the Electrochemische Fabrik Natrium at Rheinfelden; in the United States by the Roessler & Hasslacher Chemical Company; in France by the Société d'Electrochimie. The latter company manufactures sodium in their works at Clavaux (valley of the Romanche, Isere), and manufactures the cyanide at Villers dans l'Oise, the place where Gall and Montlaur carried out their process for the manufacture of potassium chlorate.

Of the 25,000 tons of the annual world production of cyanide, Germany produces one-third, of which she exports about 7000 tons; England is next with a slightly smaller amount, then comes France and the United States, which also manufacture considerable amounts of cyanide.

The Castner-Roessler process, which is the youngest in the cyanide industry, is now of greatest commercial importance; the simplicity of the apparatus and the high yield of the process allow the manufacture of cyanide at a price which defies competition. The question, however, arises, if its future is quite secure.

A new industry is in process of formation, namely that which makes use of the residues which are so cumbersome to distilleries and sugar factories. Numerous and varied products are already being extracted from these residues, for instance, trimethylamin, which is subsequently converted into cyanide. A trial plant which has been erected at Nesles (Oise) produces already 2000 tons of cyanide per year and could produce 3000 tons. When this industry will be extended to its full capacity and when other plants are erected in sugar refining and distilling centers, the production of cyanide should rapidly exceed the consumption. Cyanide will then become a by-product. The cost of manufacture will only depend on the cost of conversion (by simply heating the trimethylamin) and of the necessary soda for the absorption of the hydrocyanic acid formed:

$$(CH_3)_3N = CNH + 2CH_4.$$

Under such conditions it seems possible that the selling price be lowered to such an extent as to defy any and all competition.

# Electro-Metallurgy of Iron and Steel

BY WOOLSEY MCA. JOHNSON

So much has been written and so much has been said on the details of the above subject that it is of little use to expatiate on it. But the view "en perspectif" of an outsider should give conclusions whose usefulness may be great, according as his vision is clear. Now, the architectonics of the electro-metallurgy of iron and steel is at present somewhat ill-defined, as may be evidenced by the waiting game that iron and steel manufacturers are here and elsewhere playing.

The commercial importance of steel is greater than that of gold, silver, zinc, copper and lead combined, and indeed the trite saying that this age is the iron age is well founded. The commercial importance has a direct bearing on any electrical applications, for so important a metal has been the study of many able minds and the endeavors of many noble wills have been here adduced.

The net practical effect is that the iron blast furnace is the most efficient metallurgical instrument that exists. For instance, its thermal efficiency often exceeds 40 per cent and the saving of labor is likewise satisfactory, for a well-designed blast-furnace plant will have a charge of 30 cents per ton of ore for labor. The open-hearth and Bessemer practice has likewise been brought to a state of "temporary perfection." Economies of different nature have been introduced into the iron and steel industry, as for example, the by-product coke oven in connection with an iron works, gas engines working on blast-furnace gas, the Gailey dry-blast apparatus, and the manufacture of slag cement.

It thus can be reasoned with surety that any electro-metallurgical improvement can only succeed here because of innate fitness. The competition of the existing metallurgical art is active and severe, and more so, I believe, than is the case with any other metal. Possible and potential competition of pyro-metallurgical improvements, e. g., the oxygen-enriched blast, cannot be neglected or depreciated in a review of the subject.

Probably the only serious weakness of the iron furnace is its inability to control rigidly the quality of pig iron and the only serious weakness of the steel business is to make in quantity and at a price commensurate with the demands and needs of civilization steel of quality.

In 1902, at the Niagara Falls meeting of American Electrochemical Society, I commented as follows: "In regard to the making of steel by electro-metallurgical means, I would say that the person who attempts it competes against a 'steam-shovel' proposition. A very large part of the iron ore comes from the shores of Lake Superior, is mined by the steam shovel, is very high grade, and consequently the cost of mining, per pound of iron turned out, is very low. In the case of magnetite, I believe Mr. Ruthenburg intends to treat lean ores. In that case, the cost of mining and crushing is all multiplied by two or three, and sometimes by four or five, according to the percentage of iron in the ores. Therefore, it seems to me that any electro-metallurgical process of making steel can only be successful provided the article which is made is so much better that it compensates for its higher cost. For instance, if the steel is made very hard and free from blowholes, and has no dissolved gases in it, it has a physical texture which might compensate for its higher cost. Ordinary steel, made very cheaply, is good enough for most purposes, and steel made electro-metallurgically must be of the grade of crucible steel. Otherwise the process has no economic value." (Transactions of the American Electrochemical Society, Vol. II, pp. 99-100.)

Like any broad statement this must be construed broadly, but under such construction it still analyzes a rich percentage of truth.

While in the distant and hazy future the iron electric furnace to my mind has certain pregnant chances for general application even in such centers as Chicago or Duluth, especially as the character of future workable ores may modify the iron business, yet for the immediate future even such locations as Norway, Chile and California present but little hope of financial good fortune. The past practical success only exists as a figment of the imagination of the bold pioneer, though the present status is not unpromising in certain places.

It might be thought that with power at $6 per electrical horse-power year, approximately the thermal equivalent of coke at $8 per ton, with cheap ore and with a ready market for the product that the honest efforts of the Norwegian and Swedish pioneers would have met with marked financial success. Likewise, it is a source of wonder to me that with a market for pig iron considerably higher than that of Chicago the commercial experiments on the Pitt River, California, did not win out in short order.

With the work at Norway, the designers had too evidently copied slavishly the general lines of the iron blast furnace—simply substituting electrodes for tuyeres. This is as humorous as the first railway cars, which were merely remodeled stage coaches. If a man wishes to succeed in doing something new, he must depart from tradition while placing a proper valuation on the facts of tradition, and he must do his own thinking.

The designs at Pitt River and the designs of Helfenstein present an advance, but due regard must be paid to the following fundamental truth.

An electric furnace of buried arc or slag resistance type is much more efficient for melting than for reduction and smelting. *This principle is plain and obvious. Most metallurgical reactions require time for completion and to complete any reaction with a maximum of chemical or metallurgical smoothness a progressively intense application of metallurgical means must be used.*

There is a partial exception in case of reduction of zinc oxide by carbon, for both resultant bodies enter gaseous phase at once and in so passing out of sphere of activity give no chemical back pressure and accordingly reaction proceeds efficiently at a high rate. But what success the Continuous Zinc Furnace Company has had at Hartford in condensing 85 per cent of the zinc vapor to spelter while making a fusible slag, copper matte and lead bullion in one furnace and in one operation out of refractory ores, has been due in no small part to a proper recognition of this plain deduction from the laws of physical chemistry and electrothermics. And the moneys wasted in Canada, Norway, France and Germany, partly in large salaries and abortive large-scale experiments, has been due to an ignorance of physical chemistry, thus applied. Parenthetically, it can be stated that one for success must make his mistakes on a small scale.

It can be concluded, therefore, that the way to smelt iron ores electrically is to reduce iron oxides in gradual steps "seriatim" and produce a "sponge-iron" with incipient slagging of mineral impurities. This reduction can be done by combined influence of solid carbon, hydro-carbons, hydrogen and carbon monoxide.

If we have regard for J. E. Johnson, Jr.'s, principle that for each metallurgical condition there is a certain critical temperature at which the reaction velocity is zero and that each degree above that critical temperature the reaction velocity is increased; if we regard the action as going on in 100 or more elemental stages, and if we apply the foregoing to the progressive preheating and "metallizing" of the charge, imparting these heat units from some cheap source, e. g., from the combustion of soft coal, in a thermally insulated apparatus, electrical smelting of iron ores would not be so costly or so inefficient as heretofore. Such a process, if intelligently elaborated, has possibilities.

If by making a counter-current of ferruginous slag we were able to decarbonize and siliconize the iron and produce uniformly a pig iron approaching steel, eliminating progressively also phosphorus and sulphur, we might easily attain a commercial procedure of excellence. Unquestionably the only economic manner of electrically treating iron ores is to deliver an iron sponge to the smelting zone in balanced proportion.

The ultimate commercial method should follow closely the movement of an athlete in putting the shot. He starts the weight by force of muscles of leg, applies muscles of side and body next those of shoulder and arm, then of the wrist, and finally gives last impetus with a neat little "flick" of the fingers. The theory is to put in continuously muscular energy at a maximum efficiency and to increase continuously the velocity of the missile. When well done, it is the apotheosis of bodily grace.

Any metallurgical operation should conform as far as possible to a scheme like that of this analogy. This is well seen in the Hardinge conical tube mill, where the big particles of ore are hit by the large drop of large pebbles, and as size of particle is diminished, the drop and size of pebble hitting it is diminished.

With such a general procedure in mind and with firm control of product that electric smelting gives, there are possibilities of direct application of electrical heat to iron smelting that, though great, do not stretch one's imagination beyond the elastic limit.

Of course, one should never attempt to carry on a refining process where standard quality is desired, in a continuous operation. Where quantity or tonnage is desired, there should the metallurgical engineer employ a continuously acting process. When examining and studying the theory and philosophy of metallurgy some ten years ago, I discovered this fundamental principle: "That for concentration of metallurgical values, a continuous process is a necessity, while for refining an intermittent process is a necessity."

To my mind the fact that proper electro-metallurgy of iron consists in a graduated pre-heating with a final electric smelting of "metallized" product, making a "pig-steel" for subsequent short electric refining, is as clear as crystal. This opinion is based on some practical experience as well as on theory. The future will show how far this is right.

### The Electro-Metallurgy of Steel

There are three roads along which future progress will be made in applying electricity to steel metallurgy. Fortunately, we can record some pronounced commercial success in each line, and have generally recognized facts of the past and present on which to base hopes of the future; we have the evidences of things seen for existence of things unseen.

The three present roads are as follows:

(1) Crucible cast steel or alloy steel making.

(2) Steel castings in foundry.

(3) Super-refining of hot steel for "tonnage" steel in a steel plant.

In the first, unquestionably is the largest margin of profit. But an examination of the process for making "tool" steel does not disclose any great lack of satisfaction among user and maker. Much bad steel is sold as tool steel, but a great amount of fine steel is made in crucible to satisfaction of maker, vender and user.

Suppose a shop is using $100 worth of tool steel a year and doing a business of $20,000 a year. Does the manager want to hear about any new-fangled electric steel? He may have heard of some one using it with failure or he may have used it himself with ensuing trouble, and he has his daily problems. So he does not want to try new things. This is an extreme case, but it is an actual case. Now there are hundreds just like this and larger.

If we suppose that to introduce a new brand of electric steel, half a dozen and one fat-faced, strong-talking, stronger-eating salesmen were at hand, each drawing $5,000 or so per year and having a liberal expense account, could they do it in a year? "If seven maids with seven mops should sweep for seven year, do you suppose, the carpenter said, that they could sweep it clear?"

With such a premium on the importance of selling crucible steel, it is small wonder that the electric steel furnace which would present a new problem and offer in some cases only a few advantages, has made little headway.

Unquestionably, there are innate points of superiority in the electric steel furnace over the crucible. These can be enumerated as follows:

(1) Decreased labor charge.
(2) Dispensing with crucibles.
(3) Increased thermal efficiency.
(4) Control of temperature and chemical conditions.

All these can be summed up in fact that size of unit could be increased at will. Under (4) we might point out that the reaction between oxygen and carbon dissolved in steel comes slowly to equilibrium and that so-called "dead-killing" done in crucible can be effected much more easily in the electric furnace, and that a dense ingot can be better obtained by electric furnace than by crucible.

If we consider the electric steel furnace for alloy steel we see that its control over reductivity profoundly affects the commercial conditions in dealing with easily oxidized elements, as manganese, chromium, etc.

If I were going into the electric tool steel business, I would choose some special new field like the production of steel for mine drills. Here the advent of small high-speed hammer drill has brought a necessity for a better grade of steel, selling, say, for 8 cents per pound. This would give the newcomer more of an even chance, especially as the purchasers would buy in large blocks and would be guided by technical advice.

In arguing pessimistically in all the above, I disclaim any intention of doing anything but pointing out the general great commercial inertia and friction that confronts this and every similar innovation. My conviction of the gradual commercial success of the electric tool steel furnace is no less strong even if I see clearly the forces opposing it.

### Electric Steel Castings

In the steel castings we have much greater chances for an immediate broad expansion of the electric steel furnace. The economic freedom is great. For instance, in every industrial center there is a growing demand for steel castings from many consumers, and there is produced often by some people a large amount in the aggregate of steel drillings and turnings, "fins" from drop-forge bar plant, all of good chemical quality and all sold at a discount because of physical nature. Some of this contains oil enough to do all the pre-heating under which procedure the energy consumption would be reduced to 350 kilowatt hours per ton of product. Besides this there is often "off-peak" power that could be purchased from central stations for 7 mills to 9 mills.

Under such conditions it is perfectly possible to produce liquid steel suitable for castings for $26 per short ton; in fact this is an accomplished commercial fact. With a good-sized plant and especially favorable conditions it is quite probable that liquid steel could be made for $18 per short ton, and this is not the ultimate. The "baby" converter which uses a "high-silicon" low-phosphorus pig iron costing at an average of over $20 per ton has a serious rival in the electric furnace for production of smaller castings.

The quality of electric steel is high and its physical properties are such that with careful molding a higher percentage of merchantable finished castings can be expected. It must be realized that in any foundry careful planning of the molding work is a *sine qua non*, and the electric steel foundry should have ability equal to that of competing plant. Molding is at least 50 per cent. of the battle of the electric steel foundry.

We may even hazard the prediction that the open-hearth steel foundry has a potential competition in the electric furnace on large castings.

### Tonnage Electric Steel

In considering this subject we see that the legitimate hopes of the pioneers have been deferred. In apposition to this is the opposition to the electric furnace by the old-time steel men. This is a perfectly natural human feeling.

The adventurous-minded are a benefit to the community, but if all their apparently good schemes were put into effect, capital would be destroyed faster than it could be created. With the stupendous investments in rail, sheet, plate, wire, tube and shape mills it would be folly to suppose that those controlling such plants would care for a sudden change. For instance, if all structural material were made of electric steel, all the handbooks for bridge work must be revised, for in this work often 80 per cent. of the steel is put in to hold up its own weight, and if one can lighten one piece that enables one to decrease weight of a second, and so on.

Things that are in order must not be put in disorder, for progress should be orderly. In spite of all that the detractors of society say and because of what the busy workers in society do, things operate largely to the final benefit of the state and of each individual.

In the manufacture of tonnage steel it is natural to give this a first quick refining in the Bessemer or open-hearth furnace, pour the partially refined steel into the electric furnace, finish the refining there by use of a slag high in lime, allow reactions to come to equilibrium, the gases to pass off and the impurities to come to the top, and after this "dead-killing" is accomplished, to pour the metal into ladle. It was this accomplishment with the discovery of the "calcium-carbide" slag and the practicalization of the "series arc" furnace that was the second great contribution of Paul L. T. Héroult to electro-metallurgy.

This electric process has given new life to the Bessemer converter, and there are those that see a "triplex" process, Bessemerizing basic open-hearth treatment with final electric furnacing, as the process of the future. This may well be for certain large installations.

Certain it is that when operating in a large way on "duplex" process, the electric furnace can make steel of a superior quality at a cost slightly, if any, above the cost of that made by fire in a single operation. With the demand as pressing as it is now for "high-duty" steel rails, it is likely that the first marked commercial expansion in tonnage electric steel will be in the way of making a quality steel rail.

### Other Possible Application of Electrothermics in Metallurgy of Iron and Steel

These uses of the electric furnace are humble but none the less important, for they give an untrammeled chance for individual initiative. With control of heat possible by electric means and efficiency of electric furnace of "soaking-heat" type, it is not difficult to design an electric furnace for case-hardening, tempering or heat treatment that will work fairly well. To make one that is fool-proof and so have a ready sale is a commercial feat worthy of respect. But it will be accomplished.

The heating of forge bars has been tried. While, if made practical, it would be attractive, commercially considered, yet the practicalization of the forge-bar furnace is not yet done. In the analysis of its advantages we see the fact that no "scale" would be formed. This would save money, especially when expensive high-speed tool steel were used, in decreased loss and in saving on wear and tear of dies when hard oxide was removed from metal.

Electric welding has been in successful operation for years and is bound to expand.

Two more possible avenues of electrothermic advance remain. One of these is super-refining and superheating of cast iron for special castings. This has been tried and is proven to be promising and is in a measure successful.

The other avenue is the malleablizing of castings. It is not impossible to design a practical continuously acting pre-heated malleablizing electric furnace, and one so conceived and so developed intelligently, would have a definite sphere of usefulness for large-scale work.

In attacking and analyzing the problems in the electro-metallurgy of iron and steel one is amazed by the amount of work that awaits the investigator. This work is not in itself easy and the competition of older methods is hard. The rule should be to operate as Nature does, along the line of least resistance.

---

## Fiftieth Anniversary of the School of Mines of Columbia University

The celebration of the fiftieth anniversary of the School of Mines of Columbia University will begin on May 28 with a reception in the gymnasium, at which the alumni will be welcomed by the President of the University, the Dean of the School of Mines, the Senior Professor, Henry S. Munroe, the Chairman of the Celebration Committee and their wives, while the other members of the faculty and the committee and their wives will assist.

In the forenoon of May 29 there will be a big meeting in the gymnasium, at which President Nicholas Murray Butler will preside, and degrees will be given to prominent Alumni of the School of Mines. It is also expected that there will be sectional meetings of the various engineering graduates in the afternoon, with the first lecture in the Charles F. Chandler Foundation by an eminent chemist, at which Dr. Chandler, the last survivor of the founders of the School of Mines, will preside.

With the beginning of the next scholastic year, in September, will come the consummation of a plan conceived by the founders of the school, half a century ago—a graduate school of engineering—on the same footing as the other graduate schools of the University. Under the new plan three years of specialized study in the various branches of engineering will be offered, leading to the several technical degrees in the Schools of Mines, Engineering, and Chemistry. The requirements for admission to these schools will be the completion of at least three years of a college or scientific school course, including thorough instruction in mathematics, chemistry, and physics; and in addition certain courses in drafting, shopwork, surveying and mineralogy.

---

## Analysis of Natural Gas

BY W. D. BROWN

The analysis of natural gas has always been troublesome. In the methods in general use, the methane and ethane are exploded or burnt slowly with excess oxygen and the resultant decrease in volume and the carbon dioxide formed noted; from these the percentages are calculated. If but little, say, 10 c.c., of the methane and ethane are exploded with oxygen, any error in reading is multiplied many times. Again on combustion of a large quantity with oxygen, the resultant gas is nearly pure carbon dioxide and, its solubility in water varying with its percentage, a relatively large quantity is dissolved. The second contraction, i.e., on absorption of carbon dioxide being low, the result is that the sum of the methane and ethane obtained by calculation is over 100 and the nitrogen a minus quantity. To overcome these defects a method was devised in which the contraction on explosion and on absorption of the carbon dioxide is treated as one known factor, the oxygen entering into combination being the other factor. The explosion pipette, however, contains mercury covered with ¼ in. to ½ in. of water.

### Purity of Oxygen

The method as here given refers to the standard improved Orsat of the United States Steel Corporation,[1] but applies to any other apparatus equally as well. The determination of the percentage of oxygen in the commercial oxygen is made by exploding a large quantity of it with hydrogen and noting the resultant contraction, of which one-third equals the oxygen. This is best accomplished in the following manner: about 100 c.c. of pure hydrogen are forced into the burette, the capillary is filled with water from the explosion pipette, a reading is taken, and the gas forced into the explosion pipette until the water level is at 100; about 50 c.c. more hydrogen is then introduced and a reading is taken and the gas forced into the explosion pipette until the water level is at 100. About 60-65 c.c. oxygen are then added, a reading is taken and 15 c.c. portions are succesively introduced into the explosion pipette and exploded; after the final explosion, the residue is drawn over, the capillary being filled with water, and a reading is taken. One-third of the contraction is the oxygen, from which the percentage can be calculated.

### The Method

Exactly 100 c.c. of the gas are measured in the burette and carbon dioxide determined as usual by absorption in potassium hydrate. The solubility of the higher paraffins in fuming sulphuric acid inhibits its employment for the determination of ethylene in natural gas. Burrell (Bulletin No. 19, Bureau of Mines) uses a 1 per cent solution of palladium chloride as a qualitative test for ethylene. By placing the above solution in an Orsat absorption pipette it has been possible to make the test quantitative. Accordingly, the gas is passed three times through the palladium chloride solution, returned to the burette and measured; the diminution in volume represents the percentage of ethylene and any carbon monoxide or hydrogen in the gas. These gases are generally absent; however, their absence should be proven or the amount determined as shown later. One-half the residue is then discarded and the remaining half passed into the phosphorus pipette for the absorption of any oxygen in the gas originally or through error in sampling. While the oxygen is being absorbed in the phosphorus pipette about 130 c.c. of nearly pure oxygen are measured and transferred to the explosion pipette. This is done in the following manner: nearly 100 c.c. of oxygen are forced into the burette, the capillary is filled with water from the explosion pipette, a reading is taken, and the gas forced into the explosion pipette until the water level is at 100, the capillary being full of oxygen; about 30 c.c. more of oxygen are now forced into the burette, a reading is taken, and the gas is forced into the explosion pipette, the capillary being filled with water from the burette. The gas in the phosphorus pipette is then drawn into the burette and measured, the oxygen being thus determined. About 10 c.c. of the gas are then forced into the explosion pipette and exploded. This is repeated until all the gas has been exploded, care being taken that the last portion is well mixed before the explosion. The resultant gas is then forced to bubble through the potassium hydroxide solution and finally is transferred to the burette, the capillary filled with water, and a reading taken. The sum of the impure oxygen added and the residue exploded minus the residue after absorption of carbon dioxide is contraction "A"; or, the difference between the last two readings plus the impure oxygen added equals "A." Hydrogen is then added to the capacity of the burette and the mixture exploded and the contraction "C" noted.

---

[1] This Journal, IX, 302.

From the above contractions ("A" and "C") and from a knowledge of the amount of oxygen in the commercial oxygen, the methane, ethane, and nitrogen may be calculated, the absence of hydrogen and carbon monoxide being assumed for the time.

The reactions of burning methane and ethane are as follows:

$$CH_4 + 2\,O_2 = CO_2 + 2\,H_2O$$
$$2\,C_2H_6 + 7\,O_2 = 4\,CO_2 + 6\,H_2O.$$

From these it is seen that the total contraction on combustion and absorption of methane and ethane are 3 and 9/2 times the volume of the respective gases; or that "A" $= 3\,CH_4 + 9/2\,C_2H_6$. Likewise the oxygen consumed (Oc) is 2 and 7/2 times the volumes of the respective gases; or $Oc = 2\,CH_4 + 7/2\,C_2H_6$. Also it is clear that the oxygen consumed equals the oxygen added (Oa) minus the oxygen entering the second explosion, which is 1/3 C or $Oc = Oa - 1/3\,C$.

From these equations the following are derived:

$$CH_4 = 7/3\,A + C - 3\,Oa$$
$$C_2H_6 = (A + 1/3\,C - Oa) - CH_4$$
$$N_2 = \text{residue exploded} - (A + 1/3\,C - Oa).$$

*Example—Data.*

### Burette Readings

PURITY OF OXYGEN

| | | |
|---|---|---|
| Hydrogen added | 1.0 | 99.0 |
| Hydrogen added | 48.2 | 51.8 |
| | | 150.8 |
| Impure oxygen added | 38.2 | 61.8 |
| | | 212.6 |
| Explosion | 68.0 | 32.0 |
| | | 180.6 Contraction |
| | | 60.2 |

60.2 ÷ 61.8 = 97.4% oxygen in commercial oxygen.

GAS ANALYSIS

| | | |
|---|---|---|
| Gas measured | 0.0 | |
| Potassium hydroxide | 0.2 | 0.2 carbon dioxide. |
| Palladium chloride | 0.6 | 0.4 ethylene. |
| | 99.4 | |
| | 49.7 | |
| | 50.3 | |
| Stick phosphorus | 50.3 | 0.0 oxygen. |
| Impure oxygen | 0.6 | 99.4 oxygen. |
| Impure oxygen | 66.3 | 33.7 133.1 = 129.64 c.c. pure $O_2$ added. |
| Explosion and absorption | 77.4 — 50.3 = | 27.1 |
| | | 160.2 = contraction "A." |
| Hydrogen added | 9.7 | |
| Explosion | 63.7 | 54.0 = contraction "C." |

CALCULATIONS

7/3 of 160.2 + 54.0 — (3 × 129.64) = 38.9 = methane
(160.2 + ⅓ of 54.0 — 129.64) — 38.9 = 9.66 = ethane
49.7 — (160.2 + ⅓ of 54.0 — 129.64) = 1.14 = nitrogen

| | |
|---|---|
| Carbon dioxide ($CO_2$) | 0.2 |
| Illuminants ($C_2H_4$) | 0.4 |
| Oxygen ($O_2$) | 0.0 |
| Carbon monoxide (CO) | 0.0 |
| Methane ($CH_4$) | 77.8 |
| Hydrogen ($H_2$) | 0.0 |
| Nitrogen ($N_2$) | 2.3 |
| Ethane ($C_2H_6$) | 19.3 |

### Calorific Value

An average of the values for ethane given by Berthelot, Guldner, Thomsen, and Payne is 1760 B.t.u. per cubic foot dry gas at 62 deg. Fahr. and 30 in. mercury for the gross. The net is found by subtracting from the gross, 150 B.t.u., a value obtained from the tables of Marks and Davis. The net is then 1610 B.t.u. The net B.t.u. of methane and ethylene is 912 and 1491 respectively. The calorific value of the gas cited is then 1026 B.t.u. net. In general the gross is found by adding 1/2 $(H_2 + 2\,CH_4 + 2\,C_2H_4 - 3\,C_2H_6)$ to the net.

### Determination of Hydrogen and Carbon Monoxide

The absence of these gases was assumed in the preceding method. It is advisable to prove their absence or to determine their percentage. For this purpose, the supply of hydrogen is disconnected and a palladium tube connected to the end of the apparatus, the other end of the palladium tube is connected to an absorption pipette containing water. The palladium tube is immersed in a beaker of water at 90-100 deg. C. and oxygen passed through the tube to oxidize any hydrogen present. The water is drawn to a specified point on the absorption pipette and the capillary tube of the apparatus filled with water from the explosion pipette. Fifty c.c. of natural gas are then introduced into the burette and measured, and the carbon dioxide, ethylene, and oxygen removed as usual. About 10 c.c. of oxygen are then added and a reading taken. The gases are then passed back and forth through the palladium tube, which is immersed in hot water at first and then in cold water to cool the gas. The gas is finally brought back into the burette, the water in the pipette being at the previous level, and a reading taken. The diminution in volume is noted as contraction a. The gases are then passed into potassium hydroxide, drawn back and measured; the dimunition in volume is contraction b.

From a study of the contractions formed in the combustion of carbon monoxide and hydrogen it is seen that

$$CO = b$$
$$H_2 = \frac{2\,a - b}{3}$$

If a contraction has been found here, denoting the presence of hydrogen and carbon monoxide, or either, these contractions would have occurred in the determination of methane and ethane by explosion. In this case the sum of "a" and "b" must be deducted from contraction "A" and added to contraction "C."

Duquesne Works, Carnegie Steel Co.

**Coarse Crushing Plant of Utah Copper Co.**—The redesigned coarse crushing plant at the Magna plant of the Utah Copper Company, where 16,000 tons of ore are daily handled, is the subject of a profusely illustrated article in No. 63 of the Labor Saver, published by the Stephens-Adamson Mfg. Co., of Aurora, Ill. The entire volume of ore was formerly handled by an extensive system of cars, carrying from the bins to the crushers and thence to the reduction mill. The most important feature of the new design is the extensive use of Stephens-Adamson apron feeders and belt conveyors. The redesign is stated to have resulted in great savings.

## Radium Hearing at Washington

*[Editorial Correspondence]*

In our last issue we gave a statement of the federal-state controversy over the proposed conservation of radium-bearing ores in the United States, and showed particularly the attitude of the Secretary of the Interior and his desire to prospect for, mine and treat such ores under federal direction. Since that writing, and in deference to the protest raised by Colorado miners and prospectors, state authorities and companies interested in producing radium, the House committee on mines held a hearing in Washington, at which it sought to get full and complete information on the status of radium industry in this country. All interested parties were heard, and the record has been published.

Much of the record must be classified as light reading; it will be appreciated only by those who have a knowledge of the facts plus a saving sense of humor. There were, however, some matters introduced that will be of interest because they officially enlighten the public on points that formerly were matters of conjecture, rumor or personal opinion.

The gist of the testimony of the opponents of the federal plan of development was a fundamental objection to interference by the United States in the exploitation of the radium-bearing ores and a belief that such deposits would be best and most quickly developed by private enterprise. A point not brought out, but which is worthy of consideration, is that if the government engages in the metallurgy of radium and publishes its methods of operation, patentees of similar processes, who have devoted their time and money to the discovery of suitable methods of treatment, may be deprived of the benefits of their work. Having sought and secured the protection which a patent is assumed to offer, they may find it difficult, if not impossible, to gain the rewards to which they are entitled by their ability and energy. This complaint against government operation in the radium industry is probably worth more than most of the objections brought out at the hearing.

### The Government and the National Radium Institute

It developed early in the hearing that there was a misunderstanding regarding the relations existing between the government and the National Radium Institute. The latter is financed by Dr. James Douglas and Dr. Howard A. Kelly, who have completed a plant at Denver for the treatment of carnotite. At the hearing the motives of these gentlemen were impugned and their action was characterized as mercenary. This resulted in making public the following letter from Dr. Kelly to the Bureau of Mines, stating the terms on which a cooperative arrangement was sought and secured.

New York, October 7, 1913.

*The Director, Bureau of Mines.*

Sir: The National Radium Institute (Inc.) is a corporation duly organized and existing under and by virtue of the laws of the state of Delaware and is interested in the study of the best methods of producing uranium, vanadium and radium, and in the mining and concentration of ores from which these products may be obtained for use in radium therapy. It is interested in certain carnotite and other suitable ores mined in Colorado from which those products are obtainable.

For the benefit of the people and to secure the advantage of a scientific and technologic study of efficient methods of production, as well as mining and concentration of the ores, without waste, the institute solicits the co-operation of your bureau—that is, the services, under your supervision, of enough chemists and mineral technologists connected with your bureau as may be necessary for the proper technical control and supervision of the mining and concentration of carnotite and other suitable Colorado ores, in the study of the methods outlined and generally in the prosecution of the investigation contemplated, the results to be published by you.

To aid in such work, the institute will furnish the sum of $150,000, to be available as follows, and to be expended after consultation with us as you advise: $70,000 during the year ending August 30, 1914 · $40,000 during the year ending August 30, 1915, and $10,000 during the year ending August 30, 1916, it being estimated that about three years are required for the exhaustive investigation that is desired. The funds received from the sale of any by-products other than radium belong to us, and may also be used in the prosection of this work. It is proposed to expend this money in the mining of the carnotite or other suitable ores, to an amount of 1000 tons, more or less, of high-grade ore (over 2 per cent), or in the purchase of such ores as are necessary to an adequate study of the subject, and in the establishment and operation of a plant for the working up of said ores; also in the erection and operation of a small concentration plant for the treatment of any low-grade ore (less than 2 per cent $U_3O_8$) as may be mined or purchased, and, of course, in the payment of necessary wages of the plant operatives.

The institute also is entirely willing that any radium produced in excess of 7 grams of anhydrous radium bromide ($RaBr_2$) from any 1000 tons of carnotite ore may be donated to the bureau for further experiment or study.

As the institute has already on hand 100 tons (more or less) of carnotite, it is made a condition of this offer that this ore be first extracted far enough to demonstrate to the satisfaction of the institute the practicability of the processes employed.

Until this is done no more than $5,000 shall be expended on mining or concentration.

At the completion of this demonstration, the undersigned may withdraw from this project, and shall not thereafter be liable for any further expenditures of money other than sufficient to take up all obligations incurred up to the time of the said withdrawal, and no further demands on account of said $150,000 shall be made. All expense incurred in said transactions shall in any event be on account of said $150,000.

The institute would esteem it a favor if its co-operation should be recognized on the cover and title page of any published report of the results of this investigation.

If this proposition is acceptable, will you not kindly advise the institute as soon as you conveniently can?

Respectfully,
National Radium Institute (Inc.),
By Howard A. Kelly, *President.*

*Attest:*
Archibald Douglas, *Secretary.*

In addition to this letter, the Secretary of the Interior also introduced telegrams from Drs. Douglas and Kelly, stating that they were willing to make gratuitous transfer of the Institute's plant to the government on the termination of the three-year agreement.

The Secretary also reiterated the governmnt's intention to develop the radium industry at the earliest possible moment, and not retard it in any way nor lock up the resources of the states. His plan involved the withdrawal of some 10,000 square miles of land in Colorado and Utah, dividing this into 320-acre tracts and giving a prospector the exclusive right to search for radium-baring ores on such a tract, and to protect him in any discoveries. If ore was developed and mined the government might either receive a part or all of it for treatment, allowing the balance, if any, to reach the commercial market. No present holdings would be affected, while new prospecting would be stimulated and a domestic market assured.

### The House Radium Bill

As a result of the hearing a compromise bill has been introduced in the House. The original idea involved withdrawal and a leasing system, but this has been abandoned in an effort to harmonize the various interests. At the time of writing another hearing is in progress before a Senate committee, but it is expected that the results will not materially affect the present status, and that a bill similar to the following will be passed.

A BILL

To provide for and encourage the prospecting, mining and treatment of radium-bearing ores in lands belonging to the United States for the purpose of securing an adequate supply of radium for Government and other hospitals in the United States, and for other purposes.

*Be it enacted by the Senate and House of Representatives of the United States of America in Congress Assembled*, That all deposits of carnotite, pitchblende, or other ores, containing radium in sufficient quantity for extraction, in lands belonging to the United States, and the lands containing the same, shall be subject to exploration, occupation and purchase under the mining laws upon condition that said radium-bearing ores shall be exclusively sold and delivered to the United States as hereinafter provided, and all said ores hereafter mined from lands the title to which is now in the United States, and which were not located under the mining laws of the United States, and of the States wherein the same are situated prior to the fifteenth of January, 1914, shall be so sold and delivered, and the exclusive right of the United States to purchase and receive said ores from the owners of such lands, their lessees and assigns, together with the right of the United States to annul and void any patent issued for such lands because of failure to develop and mine such ores with reasonable diligence, shall be expressly reserved in any and all patents which may hereafter be issued.

Sec. 2. That the locators of lands containing said deposits of radium-bearing ores shall prospect, mine and develop such deposits continuously and in good faith, and failure to prosecute such prospecting, mining and development on lands chiefly valuable for said deposits for a consecutive period of four months in any calendar year shall subject the same to relocation, or in the absence of relocation, to the forfeiture at the discretion of the Secretary of the Interior: *Provided*, That the Secretary of the Interior shall have authority by public notice to suspend for such period as he may fix the requirement of continuous development as hereinbefore provided.

Sec. 3. That the sale, gift or other disposition of said radium-bearing ores to any person, association or corporation other than the United States shall be unlawful, and any violation hereof shall subject any location made or patent issued to forfeiture, and the person, association or corporation so selling, giving or otherwise unlawfully disposing of said ores shall, upon conviction thereof, be punished by a fine of not less than twice the value of the ores so sold, given away or unlawfully disposed of: *Provided*, That when in the opinion of the Secretary of the Interior special conditions arise which make such action necessary he may, by special order, permit the sale and delivery of said ores after or without tender to the United States, as he may deem advisable.

Sec. 4. That the Secretary of the Interior be, and he is hereby, authorized to erect, maintain and operate a plant or plants for the concentration and treatment of radium-bearing ores and the extraction of the radium and by-products therefrom; to purchase radium-bearing ores mined from lands occupied and held under the provisions of this Act at such prices, to be fixed by him from time to time and published in advance on the first day of January and July in each year, as will insure the prospecting for and mining of such ores, and, if need arises, to purchase or accept radium-bearing ores from other sources; to sell the by-products of such ores at the best prices obtainable; and he shall make such disposition or use of the radium produced as will best serve the need of the people of the United States.

Sec. 5. That the Secretary of the Interior shall report to Congress at the beginning of each regular session all receipts, expenditures and operations under the provisions of this Act, with such recommendations concerning future operations as he shall deem proper. All mining operations on lands located as herein provided for shall at all times be subject to inspection by authorized representatives of the Secretary of the Interior, and the locators or patentees of such lands, their lessees and assigns, shall transmit monthly to the Secretary of the Interior or to his authorized representative a statement of all developments, the nature thereof and the quantity of ore mined.

Sec. 6. That there is hereby authorized for the erection and general equipment of a suitable building or buildings for the radium extraction and other work of the Bureau of Mines in the metal mining States the sum of $150,000, and for the necessary expenses connected with the purchase and treatment of radium-bearing ores and the extraction of radium therefrom during the fiscal year ending June 30, 1915, the further sum of $300,000.

---

**Sight-Flow Indicator.**—Bulletin 57, "The Phenix Sight Flow Indicator," recently issued by The Richardson-Phenix Co., of Milwaukee, Wis., illustrates and describes how this little device can be inserted in any pipe line carrying a liquid, such as water lines of water-cooled transformers and the supply pipes of water jackets of gas engines and air compressors, and how it shows at a glance or indicates electrically by lighting a lamp or ringing a bell when the flow of liquid is interrupted. Several recent improvements in the Sight-Flow Indicator are also described, making it now possible to adjust the indicator so that it will give an alarm before the liquid stops flowing entirely, that is, when the speed drops to some pretermined minimum. This improvement has made it especially suitable for use on water-cooled transformers.

**Pickling Machines.**—Bulletin M of the Mesta Machine Company, of Pittsburgh, Pa., entitled "Mesta Improved Pickling Machines," describes these machines which have several interesting, novel features. The first is that mechanical action is brought into play to such an extent that the material is pickled with about one-half of the acid and labor required in hand-pickling. For this purpose the material to be cleaned is moved through the acid with a predetermined velocity and a slight jar at the end of each down stroke. If sheets are pickled, the jarring action at the end of the stroke separates and shifts the sheets sufficiently to allow the acid to enter between them and to prevent their sticking together. The acid washing over the surfaces has, in conjunction with the loosened particles, a scouring action which thoroughly cleans the sheets. The uniform action of the acid upon the surfaces is assisted by the thoroughness of the agitation, which does not allow acid layers of different density to form.

**The Buffalo Forge Company** has opened offices at 176 Federal Street, Boston, Mass., for its fan, ventilating and pump departments, being represented in the New England territory by Mr. B. R. Andrews, formerly with the B. F. Sturtevant Company.

# The Boiler Plant of the Blast Furnace

BY J. E. JOHNSON, JR.

In the early days of blast furnaces when tonnages were small and the quantity of iron made per cubic foot of furnace capacity was also very small as compared with present practice, the quantity of power required to drive the furnace was relatively insignificant. But even in that early day it was so considerable that plants were generally located with reference to a water power site, the gases from the top of the furnace being allowed to burn to waste in the air.

With increase in size and rate of driving, the amount of power required increased very rapidly. We shall see in a later article that this increases nearly as the square of the output of a given furnace, and that modern furnaces require from 2000 to 3000 horsepower to drive them. Consequently as furnaces were driven harder it became more and more difficult to find water power adequate to drive them. This, with the increasing introduction of the steam engine in suitable sizes and designs, and the increasing realization of the vast fuel value of the furnace gases, led to the introduction of steam power for blowing furnaces.

This step was hastened by the advent of anthracite as a furnace fuel, the pressures required with it being so much greater than they are with charcoal fuel in a given size furnace, and under similar conditions in other respects.

The question of the quantity of furnace gas per ton of iron produced and its heating value will be treated at some length in a later article, but in tracing the development of the present subject we may say that in ordinary, good modern practice about one-half of the total thermal value of the fuel charged comes out of the top of the furnace in the form of its top gases. Some 10 or 15 per cent of this heat is in the sensible condition, the rest is contained in the gas in the shape of CO, whose combustion with air gives 4370 B.t.u. per pound of CO, or 10,200 B.t.u. per pound of carbon contained.

In good modern practice there are in the average produced about 140,000 to 200,000 cu. ft. of gas, of which about 60 per cent by volume is nitrogen, and the remaining 40 per cent is made up of CO, $CO_2$ and hydrogen in varying quantities; this gas contains from 90 to 115 B.t.u. per cubic foot.

In Lake ore practice the quantity used is from 140,000 to 160,000 cu. ft. per ton of iron; the analysis approximates N 60%, $CO_2$ 15%, CO 23%, $H_2$ 2%, and the heating value 95 B.t.u. per cubic foot.

In districts where leaner ores are used and correspondingly more coke is required the percentage of nitrogen does not alter much but the CO increases at the expense of the $CO_2$ with proportional enrichment of the gas and increase in its thermal value.

In the early furnaces, and in a few cold blast charcoal furnaces to this day, this gas was allowed to escape freely from the top of the furnace, from which it burned continuously in a great flame, visible for miles at night.

The first attempts to utilize this heat for heating the blast and for raising steam were made by setting hot-blast stoves and boilers at or near the level of the furnace top, building a masonry flue completely around the top of the furnace with ports leading from the furnace top into this flue, and a powerful chimney at the far end of the combination. This chimney drew the gas, mixed with air, through the ports into the flue and thence into the boilers and hot-blast stoves. The mixture of gas and air was, of course, made at the furnace top, and so only flame was drawn through the flues.

At a later day the top of the furnace was closed by a huge inward opening valve, universally called the "bell," consisting of a cone, generally with a slope of about 45 deg., turned true in its lower portion and fitting against a similarly turned seat on the bottom of the "hopper," which in turn made a tight joint with the furnace lining, or in later times, with the shell.

All this will be described at length in dealing with the furnace top; suffice it for our present purpose to say that the charge in several portions is dumped into the hopper and rests in the bell which normally is kept closed when the charge is completed, the bell is opened long enough to allow the charge to slide into the furnace, and immediately closed. The total period during which it is open is seldom or never 5 per cent of the total time. and it is only during this period that the gas has an opportunity to escape, the remaining 95 per cent of the gas being confined and forced through the ports at the top of the furnace into the brick-lined pipes which take it to the points of consumption. In this case the furnace is kept practically air-tight, and the pressure of the gas is always somewhat greater than that of the atmosphere, to overcome resistance offered to its passage by the gas pipes, consequently when the bell is opened air does not flow in but gas flows out. As a result air never, in proper operation, enters the top of the furnace, and as the gas contains no oxygen it is perfectly non-combustible in the absence of air.

In this system, therefore, the mains carry not flame but gas, which may even be reduced to atmospheric temperature and still remain an excellent combustible.

Under these conditions the gas can be led without difficulty to very considerable distances and consequently the stoves and boilers can be located with reference to other considerations. They have accordingly, for many years past, been placed on the ground and in positions best suiting the convenience of the plant as a whole.

This gas containing, as has been said, roughly 50 per cent of the total energy of the fuel charged, supplies the heat necessary for all the operations around the plant outside the furnace itself. Its first and foremost use is for the purpose of heating the air, with which we have no present concern. This, in good practice, consumes about 40 per cent of the total gas. In first-class modern practice another 10 per cent is required for blowing power, and 5 per cent for miscellaneous purposes around the furnace, hoisting, pumping water etc., leaving 45 per cent of the gas, or nearly 25 per cent of the total energy of the fuel charged available for purposes entirely separate from the furnace.

The steam plant at the blast furnace has been until very recent years a poor and inefficient one, measured by the standards prevailing at similar periods in other lines of industry. The reason for this is not far to seek. When the closed-top furnace was introduced, and it was found that the gas could be forced by this means to any desired point within reason, it soon developed that the furnace possessed a source of power ample for its needs, even with the cheapest and simplest type of steam plant.

Steel mills at that early day were not generally built immediately in conjunction with furnace plants as they are today, and the latter, therefore, did not have in general any local market for the surplus power, and until the general introduction of electricity for lighting and power transmission there was no disposition for power except such as could be developed immediately where it was to be consumed. Hence there was no use for surplus power which might be developed by the use of economical machinery, and as this machinery was higher in first cost, and more expensive to operate than the simplest and plainest type, the latter was in almost universal use until within the last fifteen or twenty years. Slide-valve or piston-valve engines with late cut-off and little expansion, using low boiler pressure and, non-condensing, were the rule.

The boilers likewise were of the cheapest, simplest and generally most inefficient types. Plain cylinder boilers with their enormous settings and proportionately enormous air leakage were the prevailing style until within the last twenty or thirty years. These boilers were literally plain cylinders, sometimes a pair set side by side, from 3 to 4 feet in diameter and 40 to 50 feet long, entirely without flues. Sometimes there were two pairs, one above the other, the lower one joined to the one vertically above it by necks on each outside or "high" sheet, the whole suspended from two or three suspension points and exposed to the flame up to a height just below the water level in the upper cylinder, the gases making only one pass straight through to the chimney connection.

On account of their enormous water contents in comparison with their heating surface, these boilers possessed a great quantity of preserved energy, and steam pressure would not drop injuriously during a few minutes suspension of the gas supply. They were also very easy to clean because containing no tubes. Men could be put inside them and chip off the scale with chisels or with axes which, of course, is impossible in other types of boilers except as to a small fraction of their heating surface.

Other than this these old types of boilers had little to recommend them, as the great cost of the setting and the high price per square foot of their heating surface made their cost per horsepower installed about as high as that of better types.

The great increase in the tonnage of iron produced in a furnace of a given size, which might almost be said to have culminated with the Duquesne revolution, and the increase in the size of the furnaces themselves, both acted in the same direction, that of requiring a higher blast-pressure to force the desired quantity of blast into the furnace. This in turn required more power, and, therefore the practice which had been adequate if not ample for the old conditions became inadequate for the new because its consumption of steam was so great that the combustion of the furnace gas available was frequently unable to supply the quantity required. When this occurred it was necessary to burn coal under the boilers, and such coal represented a dead loss to the operation.

During the same period the integration of iron and steel plants developed extensively. Furnaces were built at large steel plants, or steel plants at furnaces in order that direct metal from the furnace might be used at the steel plant with a great saving in expense for both, the furnace sending the iron in ladles to the steel plant and so avoiding the cost of casting and handling it, while the steel plant avoided the greater cost of remelting it.

The well-equipped furnace plant having generally if not always, a considerable excess of steam at its command, advantage was taken of this fact by running a steam pipe from the furnace boilers to the steam mains at the steel mill, the latter using enormous quantities of power, but having no source of supply of its own except by burning coal or other commercial fuel.

The great value of the power so supplied became more and more appreciated and the power plant at the blast furnace was gradually improved so as to leave a larger margin of gas available for the steel mill, and this process has now gone on until some of the finest and most economical power plants in the world are those employed in blowing blast furnaces, while the subject of power development for this purpose has enlisted closest attention in Europe as well as more recently in this country.

It is a rather interesting fact that this gradual progress from the utter indifference which came from having a prodigal supply of power and no use for the surplus, to the present condition in which the expenditure of every thermal unit is watched with a jealous eye, occurred simultaneously with the development of the steam boiler from the relatively crude types, which I have described, and which were in practically universal use at one time in all other industries as well as at the blast furnace, into the modern water-tube types. First came the single-flue and two-flue boilers, then through a gradual increase in the number and decrease in the size of the flues, the multitubular boiler, which was for so many years the standard in good steam practice. Then came the later evolution, forced by rising steam pressures from the horizontal tubular boiler to the water-tube boiler, which became well established about the time the demand for more economical boilers for blast furnaces developed.

In this way blast furnaces skipped that period of development during which the horizontal tubular reigned supreme in most industries, and passed immediately from the cruder types to the modern water-tube boiler.

### Horizontal Tubular Boilers

At the Illinois Steel Works in South Chicago, where coal was expensive as compared with Pittsburgh, and where a furnace plant and steel mill were early operated in conjunction, they used at one time a great number of horizontal tubular boilers; but this is the only large blast-furnace plant, to my knowledge, where extensive use was ever made of this type of boiler. These have now all been superseded by water-tube boilers.

In New England, where fuel is expensive and where the textile mills use in the aggregate almost as much power as do the steel mills of the country so that their operators have been forced to use every possible economy in steam generation and utilization, they continue to use the horizontal tubular boiler to a great extent, even down to the present time.

It is, therefore, not on the ground of economy that this boiler has been driven out, but rather by two demands of modern practice which jointly have set conditions impossible for it to meet. These two conditions are, first, increasing steam pressure; second, a demand for large individual units so as to keep down as low as possible the total number of units for large powers. Both these conditions require heavier shells for horizontal tubular boilers, and these being exposed to the direct action of the fire their safe thickness is limited to that which will permit the cooling effect on the inside to prevent the rapid burning or cutting away of the outside, particularly at the seam with its double thickness and projecting rivets.

Water cooling is effective against the direct action of fire only within certain definite limits of thickness, and these are approximately reached in the horizontal tubular boiler at a capacity of 300 horsepower and a pressure of 125 lb. to the square inch, and though by special construction these conditions have been exceeded in horizontal tubular boilers of this type, this pressure is lower than that demanded by modern practice, and the units are smaller than is desirable in large plants. Hence the horizontal tubular boiler is eliminated from the competition.

Moreover, the question of safety is always to be considered, and while it is by no means to be thought that water-tube boilers are free from accidents, it must be admitted that the consequences of such accidents are probably on the average less destructive to life and property than those of horizontal tubular boilers.

### Types of Water-Tube Boilers

The number of types of water-tube boilers which have been introduced in the last twenty or thirty years is literally legion. Many, if not most of them, have been applied from time to time and from place to place, in blast-furnace service. Many of them are still in such service. But the development of modern plants has settled down to the use of half a dozen types, of which we may consider four.

Before proceeding to a description of these, however, a general review of the conditions of operation of boilers at blast furnace plants will not be amiss. These differ in some respects from those prevailing in ordinary insallations. First, they are normally gas-fired, though provision is always made for the use of coal should it become necessary. Second, the furnace gas with which they are fired generally contains a considerable quantity of dust which settles on the tubes and heating surfaces, and rapidly impairs their conducting power, if not removed. Third, the boilers are operated twenty-four hours a day and seven days a week. There is no stoppage of the plant over Sunday as is customary in other industries during which the boilers can be cleaned, and for this reason a sufficient reserve of boiler power must be installed to allow at least one unit to be constantly out of service for cleaning. Other than these, the conditions do not differ materially from those of economical boiler operation in general.

### General Considerations Concerning Water-Tube Boilers

The first and most important condition is, of course, that the tubes must be kept clean, not only externally but internally, and until very recent years it was practically impossible to do this in any except perfectly straight tubes. This is no longer true, but at the same time straight tubes are greatly to be preferred to curved ones, as they are less expensive and generally far less troublesome to replace than curved tubes, and in everything except length are interchangeable, which cannot be the case when curved tubes are used.

Owing to the nature of hydrostatic pressure, any vessel subject to such pressure tends to become circular, and if any other form than this is used in order to resist deformation it must be given greater strength than would be required by the circular form in a proportion greater than its deviation from the latter. For this reason flat, parallel surfaces on upper and lower drums, until recently the only ones between which straight tubes could pass, have been frowned upon by boiler insurance companies and boiler inspectors, particularly during recent years when pressures have risen far beyond what they were ten years ago, because of the difficulty of staying such flat surfaces so that they will stay flat, and the liability to excessive stresses and leakage, and even failure if they distort under pressure.

Moreover, it was for a long time very desirable to have the tubes not only straight, but to have them so set that their ends could be exposed and a cleaner carried by a rigid rod a little longer than the tube, inserted and driven through. This could not be done if the tubes were set in drums, because the drum would prevent the entrance of a cleaner so mounted into the tube. Therefore, two of the most successful of the earlier types of boilers had parallel water legs depending from opposite ends of a combined steam and water drum above, and from one of these water legs to the other ran the straight tubes. The water legs could obviously not be circular in shape and yet permit the use of straight tubes, so they were made in various ways to give the necessary strength and access to the tube ends, and at the same time permit the use of straight tubes.

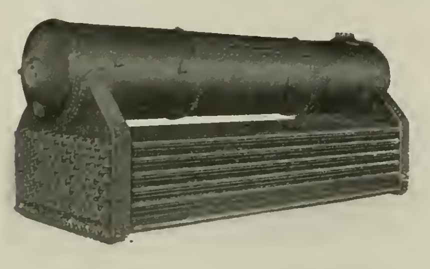

FIG. 1—THE HEINE BOILER WITHOUT ITS SETTING

One of the types of boilers on this general plan is the "Heine," built by the Heine Safety Boiler Company, and illustrated in Figs. 1 and 2. Fig. 1 shows the construction of the boiler independent of its setting. The water legs are made of flat plates stayed together by screw stays, as in locomotive-boiler construction, the perfectly flat parallel surfaces lending themselves to safe and adequate staying better than any other shape. The inner surfaces of the water legs act as the tube sheets, while holes a trifle larger than the tubes are cut through the outer surface of the water legs exactly in line with these. These outer holes are closed when the boiler is in operation with a hand-hole plate, dog and bolt, but when the tubes are to be cleaned or removed these hand-hole plates are removed and give free access to the ends of the tubes.

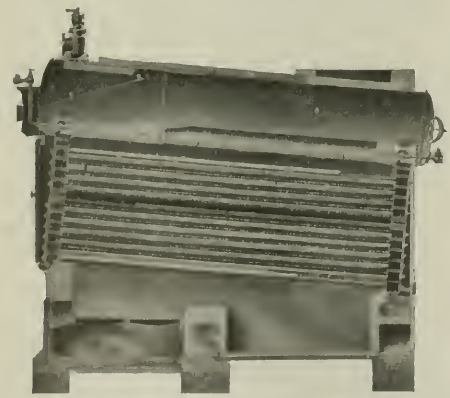

FIG. 2—THE HEINE BOILER IN ITS SETTING

The screw stays should be called stay tubes and not stay bolts, because each of them contains a hole large enough to permit the entrance of a half-inch pipe with a steam jet on the end, and as these stay-tubes are in the center of the space between the water tubes this permits the steam jet to pass down between the latter from end to end, and thus effectively blow the dust off one-fourth of each of the four surrounding the space.

This is necessary with boilers in all industries, but is particularly necessary at blast furnaces because of the great quantity of fine dust carried by the gas at the majority of plants.

The boiler in its setting is shown in Fig. 2, which also shows the baffling. It will be seen that the gases go to the rear, then to the front, and then to the rear again, passing around the drum on their way to the stack. For this reason the drum is covered with fire brick above the water line, and this is very important because I have seen the drums of this type of boiler badly burnt through failure to keep these covering bricks in place.

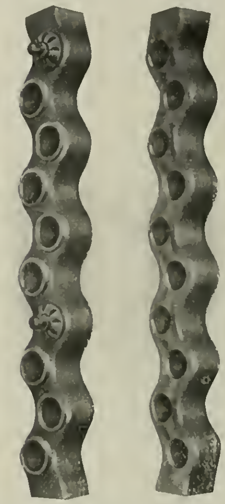

FIG. 3—WROUGHT STEEL INCLINED HEADER

Fig. 2 shows a boiler adapted only for the burning of coal, but only two minor changes are required to adapt it to burning furnace gas also. First, it should be set a little higher above the grate, and a burner opening should be provided through the front wall between the bottom of the water leg and the top of the fire arch. Second, the tiles used as baffling immediately over the fire should be of the type which completely surrounds the tubes, covering their lower as well as their upper surface, as such tiling constitutes a water-cooled fire arch. The tiles become hot enough to permit combustion, whereas the relatively cold tubes kill down the flame before the gas and air have a chance to mix sufficiently to produce complete combustion. When such gas has once been extinguished it will not reignite, but passes out of the stack unburnt and represents a dead loss.

### The Babcock & Wilcox Boiler

This boiler differs from the Heine principally in having the water leg subdivided into as many sections as there are vertical rows of tubes, this being a still further extension of the sectional idea for localizing and minimizing the effect of failure of any part. As the arrangement of the tubes in a vertical plane is staggered these headers are made sinuous, as shown in Fig. 3.

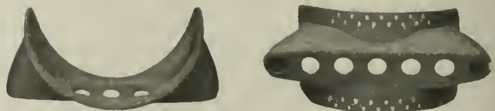

FIG. 4—FORGED STEEL CROSS BOX

Each of these headers is connected to a saddle or cross-box riveted to the drum, by means of straight tubes expanded into the top of the header at one end and into the bottom of the cross-box at the other. The cross-boxes are shown by Fig. 4.

The boiler as a whole is well shown by Fig. 5. This boiler is suspended from a structural steel frame instead of being supported directly on the brick, as is the case in the Heine boiler. Another difference from the latter boiler is that in this case the passes are at right angles to the line of the tubes instead of parallel with them.

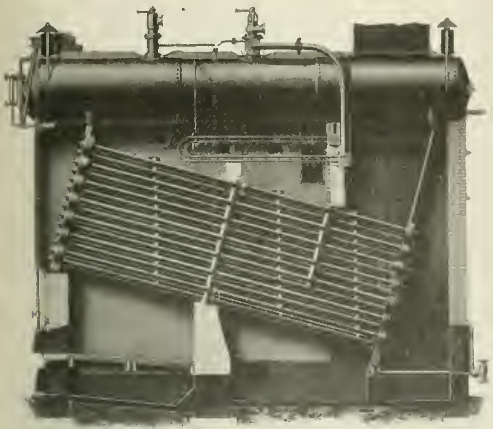

FIG. 5—BABCOCK & WILCOX BOILER IN SETTING

The baffles are built up of fire brick supported by clamps around the tubes. These fire bricks make a continuous wall with the tubes passing through it, and supporting it. One of these walls run up from the lower bridge wall, the other comes down from the suspended upper bridge wall, the passage of the gases being first up, then down, and then up again, either out above, or through the suspension tubes of the rear headers, and into an underground flue.

The arrangement of having the gas pass off upward is very much to be preferred to that in which it passes downward because the latter involves the use of underground flues, and when these become obstructed by dust as they ordinarily do in the course of a few months run, they can in general only be cleaned by shutting down the plant and putting men into them to shovel them out. In some cases the arrangement is such that a heavy stream of water can be turned into the flue and the dust washed out with this, but even this arrangement is inferior to the overhead flue, which can be provided with dust pockets through which the dust can be drawn into carts or wheelbarrows before it accumulates to an objectionable extent, and without any interruption to operation.

The boiler here shown is equipped with a superheater, this being the U-shaped coil lying on its side in the space between the bottom of the drum and the top of the water tubes. Super-heaters, as far as I know, have never ben used in blast-furnace practice, probably for the reason that they have the reputation of requiring a good deal of maintenance, and a correspondingly large number of interruptions to service, both of which would go far to offset any advantage they might produce in steam economy, interruptions to continuous service being particularly objectionable.

These boilers can be arranged for a gas firing exactly as described for the Heine, by the introduction of a gas burner immediately above the fire door, but my preference is strongly in favor of the use of a combustion chamber for burning furnace gas, and as the tiles surrounding the tubes cannot be used in this boiler because they would cut off the passage of the gas and flame completely, I am strongly in favor of the use of a Dutch oven in front of these boilers when they are to be fired with furnace gas.

Such a Dutch oven will be described and illustrated in connection with the Rust boiler, and, therefore, need not be described in detail here. In order to apply it successfully the boiler generally requires to be set somewhat higher than when no Dutch oven is used, but this is a matter of slight cost and no subsequent disadvantage.

The sinuous headers fit into each other very closely and no opportunity is permitted to introduce a steam jet longitudinally between the tubes. Consequently, in order to permit these boilers to be blown off three sets of blow-off doors are provided whose location is indicated by the three vertical rows of white dots between the tubes in the illustration. The brickwork is cut away from these doors at an angle of 45 degrees on each side, and individual blow-off holes are provided opposite the space between each two rows of tubes. By this arrangement a steam jet can be inserted between each pair of horizontal rows and also above the top one, and swung through a wide angle. By doing this from both sides the dust may be blown from the tubes quite effectively.

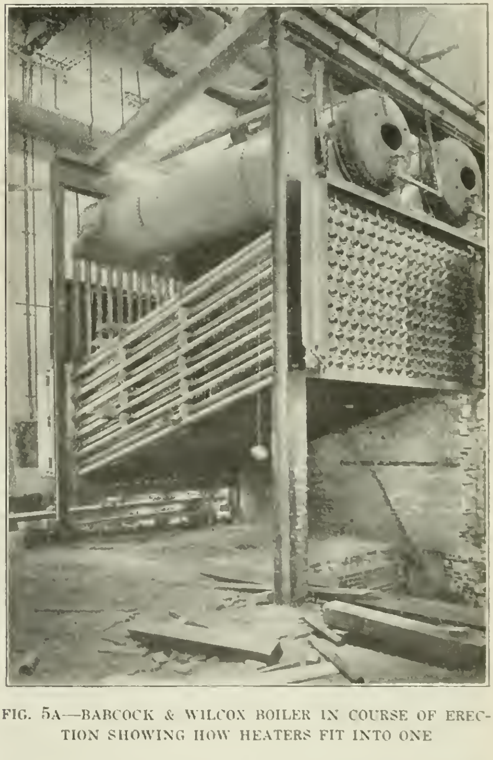

FIG. 5A—BABCOCK & WILCOX BOILER IN COURSE OF ERECTION SHOWING HOW HEATERS FIT INTO ONE

The headers are provided with holes in each side exactly like the water legs of the Heine boiler, the outside one being covered by a cap, held to place against the pressure of the steam with a bolt pulling against an inside dog. This puts the joint on the outside of the header, and these are all ground so that a metal-to-metal joint can be made.

These caps give access to the inside of the tubes for cleaning exactly as in the Heine boiler, and like it at the expense of two hand-hole joints to make for each tube, to which some operators object on account of the pains necessary to keep these joints in good order, although if they are made thoroughly tight before the boiler starts up they seldom give trouble in operation.

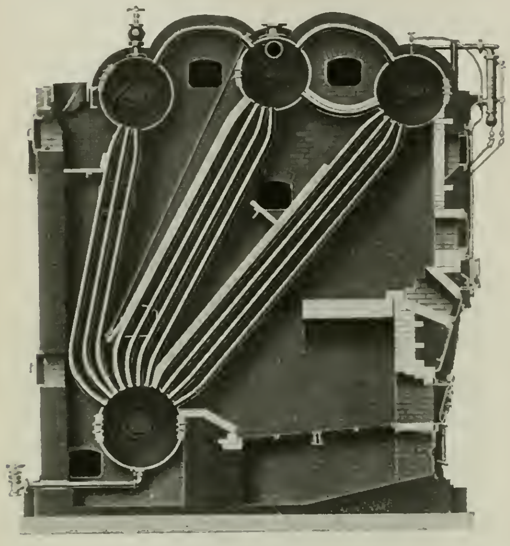

FIG. 6—STIRLING BOILER IN SETTING

### The Stirling Boiler

This boiler and its setting are both clearly shown in Fig. 6. This boiler is of an entirely different type from both the two preceding ones in two important particulars. First, there are no headers but three circular drums above and one below. From each of these three a set of tubes run to the lower one. Second, as the tubes all enter the drums radially they are necessarily curved at their ends to a greater or to less extent.

This construction eliminates the header altogether, but introduces the curved tube, and also cuts off access to the tube with a bar or cleaner of any type except a flexible one.

This for many years was the most serious obstacle to the continued successful operation of these boilers. They were furnished with scrapers mounted on chains with a weight on the end, this weight was dropped through each tube in turn and the scraper then pulled through after it. It will be seen that this was an exceedingly laborious operation, particularly as the drums are small, only 3 to 4 feet in diameter, and men could consequently only work lying down or crouched very low. The air in these drums is generally not of the best and the slightest leak of hot water from the steam connections above, or the blow-off below, makes them an almost intolerable place in which to do any work, especially the violent physical labor involved in hand-scraping.

These conditions have been very much changed by the introduction of power cleaners, which we will describe briefly at the end of this chapter.

The baffling in these boilers is inclined, but follows the line of the batteries of the tubes running to the different drums. The course of the gases is up, down, and then up through the stack connection to the draft opening just back of the rear drum. Three ordinary cleaning doors are provided above and one below, through which a steam jet can be introduced into the setting and the dust blown from the tubes, but owing to the steep angle at which the latter stand dust has not ordinarily the same tendency to settle upon them that it does on tubes that are approximately horizontal.

The bottom drum serves as a mud drum, and the sediment concentrated by the evaporation of the water gathers there, at least in part, and is blown off through the blow-off valve.

The feed takes place in the rear drum above which is entirely filled with water, and from there the feed water passes forward to the second and finally to the forward drum, there being a set of water tubes below the water line, and also steam tubes above it, connecting the front and middle drums, which serve as steam drums, particularly the middle one.

The setting of this boiler is regularly provided with a partial combustion chamber, and, therefore furnace gases may be burnt under it by introducing the burner immediately above the fire-door, but for best results with furnace gases the setting should be modified by throwing its lower part forward so that the combustion chamber would be longer.

As between the Stirling and the Babcock & Wilcox boiler some prefer the Babcock on account of its straight tubes and ease of cleaning, while others prefer the Stirling, claiming that it gives drier steam, and because it does not have a multiplicity of hand-hole plates to put on, take off, and keep tight.

### The Rust Boiler

This is the latest developed of any boiler in extensive modern use. It was invented to solve what had seemed for many years an insolvable problem, that of making a boiler containing nothing but straight tubes, and yet using only circular drums. This seemed impossible, because it is necessary for the tubes to enter the drum radially in all the older constructions, and this means that all the tubes except one row must be bent to reach this direction, as is clearly shown by the illustration of the Stirling boiler.

Mr. E. G. Rust, then chief engineer and later general superintendent of the Colorado Fuel & Iron Company, overcame this difficulty by making a forged steel tube sheet for the drum, which was circular in its principal section, but which had forged into it cup-like depressions whose axis was not radial to the drum, but in the line which the tubes were desired to have. This is shown by Fig. 7. These tube sheets are made of sufficiently heavy material so that even after the drawing necessary to form these pockets the material is amply strong.

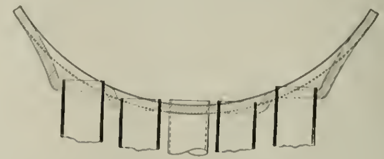

FIG. 7—RUST TUBE SHEET

The boiler in its setting is well shown by Fig. 8. It consists of four drums, two below and two vertically above, connected by five rows of straight vertical tubes. A bridge wall extends up from the foundation between the two elements of the boiler. The flame comes in on one side, passes vertically up, surrounding one nest of tubes, over the bridge wall and down, surrounding the other, thence to the stack. The bottom drums are connected by a single row of straight tubes, the top drums by an upwardly curved set of tubes for steam, and a downwardly curved set for water, the latter carrying baffle tiles to keep flame out of contact with the drums above the water line.

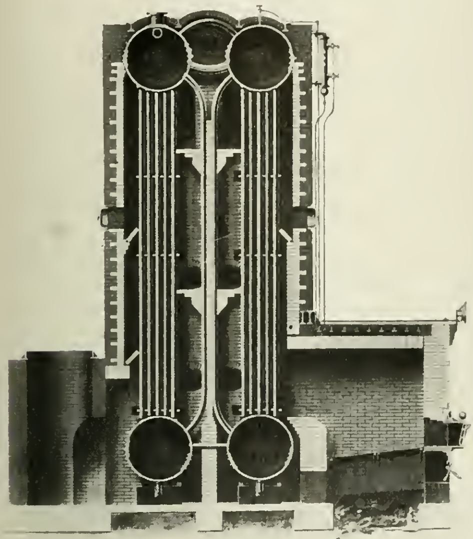

FIG. 8—RUST BOILER IN SETTING

One of the advantages claimed for this boiler is that the tubes being set vertically the dust has a minimum tendency to adhere to them, nevertheless three horizontal blow-off doors are provided which are of the same type as those described for the Babcock & Wilcox boiler, but set horizontally in this case so as to be at right angles to the line of the tubes. The setting of this boiler precludes the possibility of having the flame burn directly upward against the tubes, and owing to this construction a Dutch oven must be provided even with coal firing, which makes its adaptation to blast furnace gas very easy.

Fig. 9 shows the front of the battery of these boilers equipped with gas burners above the fire doors. The gas main may be seen in the upper right-hand corner of the illustration, and its connections to the individual pairs of burners. The valves controlling them, operated by wheel and hand-chain, are also shown.

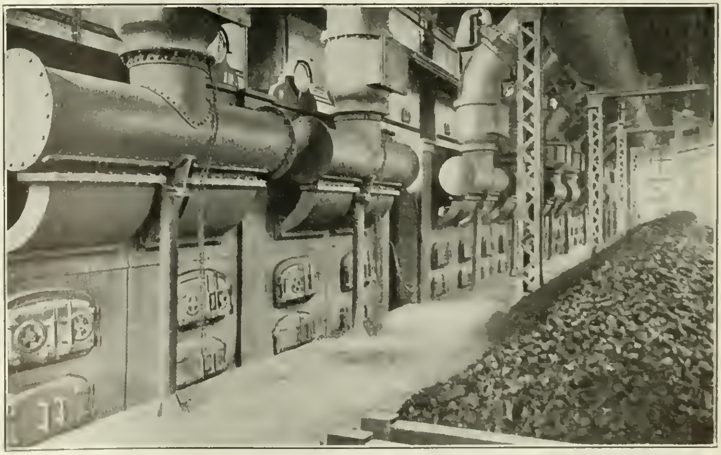

FIG. 9—SHOWING BURNERS FOR BLAST FURNACE GAS

It seems no more than fair to say that these boilers are generally preferred by blast-furnace managers who have used them above any other type.

### Gas Burners for Boilers

Blast-furnace gas is a relatively lean gas. When of the normal composition given above it requires about 60 per cent of its own volume of air for theoretically complete combustion, to which a small excess is generally added because while the losses from heavy excess of air are very great, those from unburnt combustible are still greater, and as it is impossible to maintain an absolute adjustment of air to gas it is better to err on the side of having a small excess of air rather than any considerable quantity of unburnt fuel.

In order to get the best results with the least excess of air an intimate mixture of gas and air must be made, and as the velocity of the gas through the boilers under the effect of draught is high the time for making this mixture is limited to a small fraction of a second. For this reason the entering currents of gas and air must not only be in intimate contact, but must present a maximum surface of contact for the area of opening required. This result is obtained either by the use of multiple ports for gas with air ports between, or by the use of a narrow port for gas with air on both sides. The latter is the type shown in Fig. 9.

The end of the curved flat burner projects into the front of the fire box with a clear space for air all around it. By the simple expedient of having a rectangular frame surrounding the burner and sliding on it, which can be pushed up close to the fire box front or drawn away as desired, the amount of air admitted may be varied at will, while the amount of gas may be controlled by the gas valve above. This provides independent regulation of air and gas, admitted to be a prime necessity for the most economical combustion of furnace gas.

In former times gas flues from the furnace to the boilers generally ran underground, and in these cases the burners were arranged to stand over an opening in the top of this flue. But such flues are unsatisfactory, both because of the difficulty of cleaning them out, which is still greater than that in the case of the chimney flues, and because being under the ground their tightness can never be insured, nor the amount of leakage from them determined, and leakage of furnace gas is not to be tolerated because only a few cubic feet in a large room are necessary to cause sickness and violent headaches, if not more serious consequences. Therefore, overhead mains of steel generally lined with fire brick are now commonly used, and the burners are suspended from them in some such way as that illustrated. This is a decided advantage, not only for the reasons given but because the burner is completely above and out of the way of the fire doors in case coal firing is necessary, which is by no means the case with burners coming up from below, which are not infrequently in the way at such times.

### Precautions as to Grates

When a Dutch oven or combustion chamber such as I have recommended is used the radiation from its roof or top surface is intense, while the grates are not protected by a current of air up through them as they are when coal is burned, since the air must be admitted with the gas for reasons explained above, and, therefore the ash-pit or draught doors must be kept closed.

For this reason the grates should be lightly covered with some substance such as coal, ashes or even a layer of brick laid loosely over them, to cut off the heat from above, otherwise the radiation from the arch is liable to melt them down or at least fuse shut the air openings. This would not be observed as long as the gas supply continued, but if in an emergency it suddenly became desirable to fire coal the grates being worthless none could be burned, and serious delay would result as well as the loss of the grates.

Very frequently the grates are protected by having a bed of coal spread on them which burns very slowly because no air comes up through it, the hot upper surface of which serves to light the gas instantly if the supply should fail momentarily and then start again. This is a matter of much importance, because if a mixture of gas and air fills the setting before ignition an explosion will result when ignition takes place, and the setting at least will be seriously damaged, even though the boilers are not thrown out of place and they or their steam connections ruptured. Accidents of this kind have frequently occurred, and too many precautions cannot be taken to avoid them.

### Boiler Cleaning

I have already described the earlier and cruder methods of cleaning water-tube boilers. It is not too much to say that these methods were so ineffective and the difficulty of keeping the tubes of these boilers in condition was so great that it seriously retarded the introduction of this type of boiler, because it must not be ignored that when a deposit of scale is formed inside of a tube it is reasonably secure from molestation even though the tube be taken out of the boiler bodily, so that tubes could not be cut out, cleaned off, welded up, and put back, practically as good as new, as is easily possible with the horizontal tubular boiler. This is so serious a consideration that the writer on one occasion needing additional boiler capacity installed a horizontal tubular boiler rather than contend with the difficulties of cleaning the water tube type.

In more recent years these conditions have been greatly improved for the water-tube boiler in two ways.

First, by the very general introduction at large plants which do not possess a natural supply of good boiler water, of purifying plants which neutralize any injurious acid which the feed water may contain (which in coal mining regions is sometimes a very large quantity), and then, by the addition of some suitable chemicals, precipitate out a large part of the scale forming material which the water contains, and throw that which is left into a form which makes sludge and can be blown out. Without such treatment this material settles on the tubes and other heating surfaces in a deposit almost as hard as iron, and almost as non-conducting as asbestos.

Second, by the introduction of power-driven boiler cleaners of various types. Generally the power is transmitted to the cleaner, either by water under pressure or by compressed air, the fluid under pressure in either case drives a motor of a size small enough to go inside the tube and pass through it freely. This motor carries at its forward end steel cutters of various forms, generally loosely pivoted to the shaft of the motor and thrown out to the wall of the tube by centrifugal force.

The motor is run at a very high speed and the rapid whirling of these cutters removes the scale which is carried out of the tube by the "exhaust" of the fluid which drives the motor.

Much ingenuity has been employed both in making and in selling devices of this kind, and some of them are extremely meritorious. The motors in general are of two types, turbine and sliding vane positive-pressure motors. It would be thought that this would be the ideal field for the turbine but I have obtained the best results with the sliding vane positive-pressure motor.

As between the two fluids, water and air, the advantages, in my judgment, are so strongly in favor of compressed air as to put it beyond comparison. This is for two or three reasons. First, the men working with the apparatus are at close quarters with it in a confined space, and no matter how carefully made and operated water-driven apparatus may be under such circumstances, it is impossible for the operator to avoid becoming wet and very dirty from the sludge produced by the grinding up of the scale. This makes the task an excessively disagreeable one for the operator, and reduces his speed in working at it materially. Secondly, the exhaust water from the motor cannot be prevented from reaching the brick work of the setting to a greater or less extent, and in the Babcock and Wilcox boiler it is almost impossible to prevent its running down into the underground flue with a bad effect upon both the draught and the flue.

With air none of these disadvantages exist. The air is perfectly clean, and its expansion even tends to cool to a small extent the air in the drums which the operator has to breathe, so actually ameliorating the conditions under which he has to work, while, of course, it has no effect whatever on the setting. Moreover, the amount of power needed may be transmitted through a much smaller hose with compressed air than with water, and, therefore the hose which connects the motor with the supply of power, and by which it is pushed through the tubes, is correspondingly smaller, lighter and easier for the operator to handle.

By the use of the best types of these cleaners boiler tubes can be kept clean at a fraction of the expense and with a fraction of the time lost from service that are required when hand-cleaning is used.

Moreover, it is very much to be doubted whether hand-cleaning ever cleans the tubes so thoroughly as do power cleaners no matter how conscientiously the former may be done.

I have seen the power cleaner applied to boilers supplied with the best natural feed water which had received the most thorough care, were thought to be absolutely clean, and were as far as could be seen, but at certain points the cleaner found and removed scale a quarter inch or more in thickness, which had been entirely invisible from the ends, although these were straight tubes.

Owing to the short length of these cleaners they may be used on curved tubes as well as straight ones and are equally effective therein.

This goes far to remove the disadvantage under which the Stirling and other curved-tube boilers formerly labored and to put them on a parity from an operating point of view with the straight-tube types. Of course, this does not remove their disadvantage in the matter of removing and replacing tubes.

The power boiler cleaner is like many other useful tools in that it must be used with care and discretion. In order to cut the scale the cutters must be good tool steel, almost as hard as glass and very sharp. In order to be effective they must run at a speed of many hundred revolutions per minute. It is obvious that if allowed to run in contact with the bare tube in one place they would soon cut it away enough to weaken it seriously if not to cut it through entirely, and the operator must be carefully instructed and advised to prevent this.

These two developments of the past decade and a half—the feed-water purifying plant which keeps out of the boilers much of the scale-forming material, and the power-drive tube cleaner which removes that which gets in—have reduced to a fraction of their former amounts the time, labor and expense of boiler maintenance, increased their average efficiency and decreased the percentage of spares necessary. They have thus gone far to solve the problems of boiler operation at blast furnaces.

## Notes on Chemistry and Metallurgy in Great Britain

(*By Our Special Correspondent*)

### Oil Shale in Skye

The shale deposits in the Island of Skye, which were described in a recent letter, have been further examined by boring, and although the shale thus obtained shows a considerably higher value than the samples taken when the announcement of the discovery was made last August, yet they are not rich enough to warrant the hope that the deposits can be worked profitably at present. The specimens taken in August were obtained from very badly weathered outcrops, and, of course, showed a very poor oil content. Lord Macdonald, the owner of the island, consequently had five borings made, and the samples from these show a yield of only some 19 gallons per ton—a result which can only be considered disappointing in view of the fact that in the Lothians a paying shale would produce quite 30 gallons per ton. It is possible, however, that some portions of the deposits in Skye may be of a better quality, and it is expected that further investigations will be made.

### Corrosion of Iron and Steel

Mr. F. Crosby-Jones recently read a paper before the Institute of Mining Engineers on "The Corrosion of Iron and Steel," and while he did not contribute anything new to the various theories of the cause and nature of corrosion, he made some valuable suggestions as to the practical methods of prevention of corrosion. He advocated that the same class of metal should be employed throughout all structures as far as possible, and that surfaces should be rendered smooth and without any depressions, pockets or cracks, which would be capable of retaining water. Free access of air to all members should be provided, and arrangements should be made for any necessary drainage of water. Special attention should be given to joints, rivet-heads, nuts and bolts to effect complete exclusion of wet and moisture, while a most careful inspection of all parts which were not easily visible was most essential. With regard to painting, inspection would be much facilitated by having each coat of a different shade, and a check could be more easily kept on the number of coats supplied. Perhaps the most important point was that the metal should be thoroughly cleansed and dried before any protective coating was put on, and even then it was necessary to employ a good and suitable material and to insure that the work was efficiently done.

### The Progress of the Electric Furnace

It has been generally supposed that British smelters and refiners have shown considerable reluctance to adopt the electric furnace, but statistics go to show that after all they have not lagged very much behind other countries. There are now 14 electric furnaces at work in England, 13 in France, 20 in Italy, 17 in the United States and 32 in Germany, besides a few in other countries, making a total for the world of something between 140 and 150. A remarkable fact is that in Germany 50 per cent of the furnaces are of the induction type and 50 per cent of the arc type. Out of the 20 Italian furnaces 19 are arc, as are 10 out of the total 13 French, and 13 out of the 14 English. The Heroult, the Girod, and the Stassano are the arc furnaces most numerously adopted, while the Kjellin and the Röchling-Rodenhäuser occur most frequently in the induction installations. The progress in Scandinavia is shown by the fact that Norway and Sweden employed only nine furnaces for the smelting of pig iron in 1912, and had more than doubled the number by the end of the following year, when 20 furnaces were in full operation.

### The Institution of Mining and Metallurgy

On the 13th of January the Institution of Mining and Metallurgy entered into possession of its recently acquired premises in Finsbury Circus, when the Lord Mayor performed the opening ceremony on the 22nd anniversary of the foundation of the institute. The membership has risen from 585 in 1899 to 2372 last year, and for some years the necessity of finding more extensive accommodation than was afforded by the old headquarters at Salisbury House has been increasingly apparent; but it is not always easy to find suitable premises in just the locality of the city in which the mining industry predominates. The building has been entirely renovated throughout, but the main architectural features have been interfered with as little as possible. The president, in calling on the Lord Mayor to open the building, said he wished to remind his hearers that practical metallurgy was very largely represented in London by extensive refining of gold and silver. The weight of gold melted at the Royal Mint and some other refineries amounted to 508 tons in 1812, and London was still in the proud position of being the only free market in the world for gold. It was their intention to present a petition to the King for a Royal Charter of incorporation by which the corporate existence of the members as metal miners and metallurgists would be recognized. The Lord

Mayor was then presented with a gold key, the wards of which were fashioned from the institution's initials.

### The Absorption of Gases by Celluloid

At the December meeting of the Chemical Society Mr. Victor Lefebure read a paper in which he stated that he had observed in celluloid an absorption of gases comparable with the absorption of gases by some kinds of charcoal. The effect was of the reversible order, and was not chemical because there was not any formation of a compound with a very low or moderately large dissociation pressure—it being assumed that such compounds would not form solid solutions with celluloid. The absorption occurred with all varieties of celluloid examined and reached a minimum in the case of a precipitate of celluloid constituents; but when this precipitate was reformed into a film the absorptive property recurred. The two chief constitutents of celluloid, nitro-cellulose and camphor, do not exhibit absorption. The effect was inversely as the temperature and directly as the pressure; and, in its general nature resembled a case of sorption. Diffusion experiments have established the fact of diffusion through films.

Professor Donnan, in the discussion, said that the rapidity of the initial absorption of carbon dioxide and the fact that the increase of the speed of absorption per unit weight of celluloid was greater than the increase of surface went to show that there was in the body of the celluloid—perhaps near the surface—a very fine-grained macro-porosity into which the gas could readily penetrate and be there absorbed.

Mr. W. P. Dreaper remarked that the porosity of structureless cellulose filaments could be widely varied by varying the strain to which they were subjected during the drying process of their manufacture.

### A Substitute for Petrol

Professor Vernon Boys, the well-known authority on gas-work chemistry and engineering, has devised and carried out a process for the commercial production of motor-spirit from heavy mineral oil waste, and states that the product is at least equal to ordinary petrol as fuel for motor engines. The heavy waste, heated to a fixed temperature, is subjected to the intimate action of steam, at 315 deg. C., which is then circulated through heated tubes containing a series of nickel rods. Hydrogen is liberated from the steam and combines with the finely divided particles of oil forming a substance closely resembling natural light petroleum spirit or "ligroin." The process is said to yield over 40 per cent of spirit from the crude waste: and the gaseous hydrocarbons which are also produced can be used for heating the tubes containing the nickel rods. A tarry residue remains and is available for further treatment or for other uses; and possibly—provided that a sufficient supply of waste oil were obtainable—the recovery of by-products might become worth attention.

### The Prevention of Scale in Boilers

A new device has been brought out under the name of the Vapor Scale Collector for which a high degree of efficiency is claimed in removing from the feed water those dissolved substances which under ordinary conditions contribute largely to the formation of scale.

The apparatus is simple, and consists of a series of partially perforated trays divided into compartments fixed in the steam space of the boiler and arranged so that the feed water passes in a cascade from the top tray to the bottom one with a wavy motion and at a rate which insures its attaining a temperature of 300 deg. F. before reaching the boiler water, when the feed is continuous and the boiler pressure not less than 85 lb. per square inch.

At this temperature carbon dioxide and dissolved air are completely expelled from the water, and a very large proportion of the scale-forming solids usually found in ordinary waters is deposited in the trays as mud and under them as stalactites. But, of course, most of the calcium sulphate, which goes to form hard scale, would not be thrown out of solution.

### Engineering Imports and Exports

The returns issued by the Board of Trade for the twelve months ended on December 31, 1913, show a very substantial improvement on the figures for 1912 in all classes of engineering materials and manufactures, especially with regard to exports. Imports of iron and steel, including manufactures, amounted to £15,230,694, an increase of £2,268,703, and exports totalled £54,328,292, an increase of £5,730,615. Other metals, including manufactures, were imported to the value of £32,102,246, a rise of £904,818, and were exported to the value of £13,288,350, an improvement of £1,003,879. Imports of electrical goods reached £1,587,318, and exports £5,404,671; the respective increases being £129,675 and £1,063,084. In machinery the imports were £7,282,046, a gain of £461,363; and exports went up to £37,027,582, which is a rise of £3,869,567.

The figures for the month of December alone are not so satisfactory. Imports of iron and steel increased by £208,139 on the value for December, 1912; but exports were £229,874 lower; imports of other metals fell £497,704, and exports decreased £126,979; imports of electrical goods rose £18,083, and exports were £26,345 higher; imports of machinery were only £3265 better, while exports improved by £214,122; new ships rose £1,171 in imports, but exports declined £394,484.

### Market Prices

*January*, 1914

| | £ s. d. |
|---|---|
| Aluminium ingots, in ton lots | 90. 0. 0 |
| Alum, lump, loose, ton | 5.10. 0 |
| Antimony, Star Regulus, ton | £28 to 30. 0. 0 |
| Borax, British refined crystal, ton | 17.10. 0 |
| Copper sulphate, ton | 22.10. 0 |
| Caustic soda, 70%, ton | 10. 5. 0 |
| Copper ore, 10 to 25%, unit | 11/ to 11. 6 |
| Ebonite rod, lb | 4. 6 |
| Hydrochloric acid, cwt | 5. 0 |
| India-rubber, Para, fine, lb | 3. 2½ |
| Mica, in original cases, medium | 3/6 to 6. 0 |
| Petroleum, Russian spot, gal | 9¼ |
| Quicksilver (Spanish) bottle | 7.10. 0 |
| Sal ammoniac, cwt | 2. 2. 0 |
| Sulphate of ammonia, ton | 12.10. 0 |
| Sulphur, recovered, ton | 5.10. 0 |
| Shellac, cwt | 4. 2. 0 |
| Platinum, oz., nominal | 9. 5. 0 |
| Tin ore, 70% ton | £103 to £105 |
| Zinc, Vielle Montagne, ton | 25. 0. 0 |

| *Higher* | £ s. d. | *Lower* | £ s. d. |
|---|---|---|---|
| Tin, ton | 10. 0. 0 | Borax, ton | 1. 0. 0 |
| Scotch pig | 7¼ | Sulphate of ammonia | 10. 0 |
| Cleveland | 9½ | Shellac, cwt | 6 |
| Lead | 2. 0. 0 | Zinc, ton | 12. 6 |
| Ebonite rod | 6 | | |

Copper opened £64 10s. 0d. and declined till the 9th, when it had reached £62 17s. 6d., recovering slightly on the 12th, it afterwards fell slowly, reaching £62 12s. 6d. on the 14th, and then recovered, rising until £65 7d. 6s. was touched on the 23d, and £66 on the 30th.

Tin opened £168 and fell away smartly to £166 10s. 0d. on the 5th, recovered on the 6th to £168 10s. 0d., and was £167 on the 8th and £167 5s. 0d. on the 14th, with recovery between. From the 15th, however, it became stronger, rising to £173 7s. 6d on the 21st and £177 on the 22d; the 23d saw a drop to £174 10s. 0d., and its subsequent recovery to £176 15s. 0d. on the 26th and £180 on the 30th.

# Symposium on the Undeveloped Elements

## Factors Involved in Opening Up the Field of Unused Elements—Papers on Cobalt, Boron, Ductile Tungsten, Selenium, Tellurium and Cadmium

The joint meeting of the New York sections of the American Electrochemical Society, the American Chemical Society, and the Society of Chemical Industry, held on the evening of Feb. 6 in the Chemists' Building in New York City, was exceedingly well attended in spite of the inclement weather. Mr. Lawrence Addicks, chairman of the New York section of the American Electrochemical Society, presided. The subject of the evening was a symposium of papers on "Undeveloped Elements."

Chairman Addicks in opening the meeting pointed out that "the number of known chemical elements is rapidly increasing and it is open to debate whether some of the brilliant work done in identifying new elements were not better applied to learn how to turn some of these already known to the use of mankind.

"In the earliest times we have the single conception of the unity of matter, which, strangely enough, we once in so often consider as still a possibility in explaining new discoveries. Then came the artificial classification of the early Indian and Greek philosophers, which were not rejected until shortly before the Christian era, at the beginning of which seven of the metallic elements were known—copper, silver, gold, tin, lead, iron, and mercury. The whole span of the middle ages and alchemy yielded but ten more elements, giving us a total of seventeen about 1750 at the beginning of Lavoisier's work. Sixty-seven elements were listed in Remsen's Chemistry of 1891. In the 1912 International Table there are eighty-two, and the end is not yet.

"Now I submit that a man's responsibility for an element should not end when he has proved his discovery by finding an atomic weight not already preempted and christened it with a name like a Pullman car, but that he should stay with it until he finds what it is good for. On the manufacturing side we have a similar situation. Many a concern will spend unlimited money to find just what substance will show certain desired properties, but, strangely, is unwilling to spend any money to develop uses for an apparently worthless by-product."

Mr. Addicks then introduced the first speaker, Dr. Charles Baskerville, who for years has made a special study of the less common elements and has conducted many researches along unused elements.

### Factors Involved in Opening Up the Field of Unused Elements

Dr. Charles Baskerville, professor of chemistry and director of the laboratory of the College of the City of New York, introduced his paper by giving two convenient tables "confessedly imperfect and based on capricious opinion." In the first table elements are given which are little used or are not used at all, while their compounds are used more or less. In Table II elements are given which are unused or little used both as elements and compounds.

TABLE I.—ELEMENTS LITTLE USED OR NOT USED, BUT WHOSE COMPOUNDS ARE USED MORE OR LESS

| 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | Unclas. |
|---|---|---|---|---|---|---|---|---|---|
| | Li | Mg | B | S | As | | F | Co | |
| | K | Ca | | Zr | | | Br | | |
| | | Ba | | Ce | | | I | | |
| | | Ra | | Th | | | | | |

TABLE II.—ELEMENTS OR COMPOUNDS UNUSED OR LITTLE USED

| 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | Unclas. |
|---|---|---|---|---|---|---|---|---|---|
| He | Rb | Be | Sc | Ge | Cb | Se | | Ru | Pr |
| Ne | Cs | Sr | Y | | Yb | Te | | Rb | Nd |
| A | | | La | | | | | Os | Sm |
| Kr | | | Ga | | | | | | Eu |
| Xe | | | In | | | | | | Gd |
| Nt | | | Er | | | | | | Dy |
| | | | Tl | | | | | | Tm |
| | | | | | | | | | Lu |
| | | | | | | | | | Tb |

About one-half of these have been discovered within the last thirty years. Those so recently made known are usually classified under the two groups of "rare gases" and "rare earths." The latter group is further conveniently subdivided under the heading of "rare earths" as follows:

TABLE III.—RARE EARTHS

| Ce Group | | Tb Group | | Yt Group | |
|---|---|---|---|---|---|
| Element | Atomic Weight | Element | Atomic Weight | Element | Atomic Weight |
| Sc | 44.1 | Eu | 152.0 | Dy | 162.5 |
| Yt | 89.0 | Gd | 157.3 | Ho | ? |
| La | 139.0 | Tb | 159.2 | Er | 167.4 |
| Ce | 140.25 | | | Th | 168.5 |
| Pr | 140.6 | | | Yb | 172 |
| Nd | 144.3 | | | Lu | 174. |
| Sm | 150.4 | | | | |

Dr. Baskerville called attention to the melting points and specific gravities of four of them.

Melting points: Ce = 623 deg. C.; La = 810 deg. C.; Nd = 840 deg. C.; Pr = 940 deg. C.; Al = 660 deg. C., and Ag = 960 deg. C., which gives a standard of comparison.

Specific gravities: La = 6.15, Pr = 6.48, Nd = 6.96, Ce = 7.04.

"Cerium has about the same density as Sn (7.3), but all of them readily oxidize on exposure to air. Cerium is between lead and tin in its physical appearance and harder than tin, while lanthanum acts much like metallic calcium, its oxide combining readily with water to form the hydroxide, being even air slacked (combining with carbon dioxide) as does lime." Dr. Baskerville exhibited small samples of these metals prepared in his laboratory, and in passing stated that the price of metallic cerium in Germany has fallen from 250 to 20 marks per kilo.

"The word 'rare' as applied above—as is the case with so many words of qualification—has changed its meaning in the light of very recent investigations, although the 'rare gases' are found in the atmosphere in the following proportions:

TABLE IV.—NOBLE GASES

| Name | Atomic Weight | One Part by Volume in Air |
|---|---|---|
| Helium | 4.0 | 2,450 volumes |
| Neon | 20 | 808 " |
| Argon | 39.9 | 105 " |
| Krypton | 81.8 | 746,000 " |
| Xenon | 128.0 | 3,846,000 " |

"Some of the elements mentioned above are by no means so uncommon now and may be had in commercial quantities." Table V contains these and some other elements, many of which have been known for a long time, not now used extensively, but inviting application.

TABLE V.—ELEMENTS NOW AVAILABLE, OR EASILY RENDERED AVAILABLE, IN COMMERCIAL QUANTITIES, BUT LITTLE USED

| 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | Unclas. |
|---|---|---|---|---|---|---|---|---|---|
| A | K | Ca | B | Si | As | Se | Br | CO | |
| | | Sr | Y | Zr | Cb | Te | I | Pd | |
| | | Ba | La | Ce | Ta | | | | |
| | | Cd | | Th | | | | | |

### FACTORS INVOLVED IN BRINGING THE FIELD UNDER CULTIVATION

"Let us see what are some of the factors involved in bringing the field under cultivation. I know how hard the work is. I have been a field hand for, as McIver once said, 'I've ploughed new ground with a blind mule.'

"In some cases we lay the lack of use of the elements at once to the scarcity of known occurrences. Haber has shown that osmium is the best catalyzer for making ammonia from its elements, but von Welsbach, who devised the osmium-filament lamp, has calculated that there are only a few hundred pounds of osmium available in the periphery of our globe. When, however, we remember that carbon is but 0.21 per cent, while silicon is 25.3 per cent of the crust of our earth for a depth of ten miles including the waters on the earth and its surrounding atmosphere, according to Clarke's calculations, we know that our present utilization of the elements commercially bears but little relation to their total quantity.

"With some striking exceptions, man has found more or less ample sources of the elements or their compounds when it has been shown that our civilization required them. I need but mention tungsten, thorium, vanadium, and radium in illustration. It is not the small percentage in which these elements occur, for palladium exists in nickeliferous pyrrhotites in quantities too small to be detected by even refined chemical analysis, but it accumulates in the slimes of nickel refineries and is thus obtained in some quantity. The price fixed by possession is the deterrent in the development of the use of palladium, a fact of no individual immorality, but contrary to the law of economics.

"Some ten years ago one large corporation possessing a store of palladium was approached by some technologists supported by good repute, with the idea of working out uses for that by-product. The owners said they were not interested in spending a thousand dollars on the investigation—they did not mind spending the money, but they would not be a party to lowering the price of the material in their possession, the inevitable result of extending its use. This principle is well illustrated in the history of metallic aluminium and thorium oxide whose market quotations have fallen to one-hundredth and two one-hundredths, respectively, what they were one generation ago.

"On account of its great resistance to atmospheric oxidation and moisture and to the effect of sulphuretted gases, palladium has been employed for the inner mechanism of chronometers and watches, for the construction of fine balance beams, for the divided scales of delicate apparatus, for surgical instruments. It has been used for coating silver goods, and for electroplating searchlight mirrors, for soldering platinum, and in dental preparations. Palladinized asbestos, palladium sponge and palladium black are most efficient catalytic substances for reducing purposes. This well-known fact may be flashed from the housetops without any fear of coagulating the clouds of litigation hovering over the oil-hardened situation in this country, as the parties referred to still own the palladium.

"Some of these 'unused' elements will be used if the prices are made more reasonable. A very important factor in reducing the market prices of these substances is an improvement in methods of extraction. This I may illustrate from the group of rare earths, not that I mean to lead you into that maze, but because it shows how modern tools have served the purpose and gives suggestions for needed extension with other elements among the 'meta-elements,' as Crookes termed them.

"Monazite sand is essentially a phosphate of the rare-earths containing valuable amounts of thorium, usually 4 to 6 per cent. The problem of obtaining thorium compounds from that source—315,000,000 Welsbach mantles was the world's output in 1913—depends upon (1) solution, usually by baking, with concentrated sulphuric acid and leaching. Very fine grinding of the sand was essential. (2) The rare earths and thorium are then thrown out as oxalates to remove the last trace of phosphoric acid. (3) The mixed oxalates were brought into solution with the destruction of the oxalic acid and the thorium precipitated or the oxalates were treated with ammonium oxalate whereby the non-hydrated thorium tetra-ammonium oxalate went into solution. This thorium salt was subsequently converted into nitrate. With all the price of thorium salts steadily declined until it seemed to reach a limit.

"Muthmann and Weiss conceived the plan of distilling of the phosphorus and converting the metallic elements present into carbides. The resultant mass is hard and is very expensive to grind in order subsequently to dissolve it. The writer later produced calcium carbide within the mixture of other carbides, using the unground monazite sand. This mass when thrown into water crumbles at once to a powder from which the suspended milk of lime is readily washed. The residual mass goes into solution in commercial hydrochloric acid from which the thorium may be precipitated at once in a form readily soluble in the nitric acid. The cerium may be thrown out of the solution from the thorium precipitate and tons of oxalic acid are now destroyed or locked up in the by-product of rare earths which are accumulating awaiting the development of uses.

"Muthmann and Weiss have applied the Hall process for the isolation of metallic cerium, whose use is now practically limited to pyrophoric alloys.

"Very recently it has been proven to be distinctly profitable according to separate patents of Soddy and Hahn, to separate meso-thorium compounds in the process of extracting and purifying the thoria. Mesothorium rivals radium in some of its applications in radio-surgery.

"The three instances cited above are given for another reason. The ideas were worked out by three college professors. Laborers must be provided for clearing the field, whether the toil be that of working out new processes to so reduce the cost of a material as to admit of its application to uses already known to exist or devise uses not known for by-products now quoted at fictitious prices, but which do not appear at such suppositious values in the annual financial statement.

"Undoubtedly the best way to work out problems of the utilization of 'undeveloped elements' is to attack them in such well-equipped and splendidly manned research laboratories as are maintained by the General Electric Company, the General Chemical Company, the Eastman Kodak Company, and others, but their upkeep involves large expenditures. Many colleges and university professors would welcome a subsidy work of this character, which should be scientific, dignified and help keep the wolf from the door. I commend for your amusing perusal 'The Confessions of a College Professor's Wife' in a recent number of the *Saturday Evening Post.*

"I do not mean that the college professor is prepared to or should go into the factory, but he can work at an idea, which should later be developed, if it has merit, on a commercial scale by the technical chemist or chemical engineer. Elaboration of this proposition, which is not novel with the speaker, is not necessary here. Suffice it to say that one so selected would bring to the problem a degree of ignorance that might be stimulating and a freedom from tradition which would admit of a display of imagination necessary to utilize material which is commercially abundant and inviting investigation.

"H. B. Baker has said somewhere, 'Nothing can be of more value to science than the exhaustive study of one particular action.' Weiss and Neumann have found that compressed zirconium is a conductor, whereas previous statements have been that it was non-conducting. There is need of reviewing many such statements that are handed down in the literature. Aluminium is sonorous, as according to so many textbooks. I have a sample of very pure aluminium, a part of which was used by Mallet in the determination of its atomic weight, and, as he assured me, it is not sonorous. If aluminium is sonorous it is not pure.

"Stewart in his charming book on 'Recent Advances in Physical and Inorganic Chemistry' in referring to 1887 and the following years of feverish activity in physico-chemical research, led by Arrhenius, Van't Hoff, and the elder Ostwald, says: 'To some extent, this wave appears to have spent its force. At the present day physical chemistry, except in the hands of a few exceptional researchers, has degenerated into a means of attacking the problems of pure chemistry instead of opening up new fields; and consequently there is a certain tendency to decry the subjects as a means to an end, and not a living branch of science. This is perhaps an exaggerated view; but it cannot be denied that physical chemists of the present day are not animated by the high hopes which seemed to have inspired Ostwald and others in the earlier days of the subject.' Bancroft acknowledges that there is some truth in this criticism, but asserts 'The difficulty is that most people are still struggling under the limitations imposed deliberately and consciously by Ostwald. Once these are broken through, nobody will have any cause to complain of the wave having spent its force.'

"Stewart further says: 'It is an extremely fortunate coincidence that as the first movement declined, a second and perhaps more powerful one had succeeded it. This second movement rose with even greater rapidity than pure physical chemistry, and yet at the present day we appear to have touched only the fringe of the subject of radioactivity; so that we may look forward to a long career of fruitful investigation still before us in this department of chemistry.'

"The problems of sub-atomic or electronic universe have presented themselves and at once we begin applying these new ideas to utilitarian purposes. The cryogenic laboratories have accumulated fractions from tons of liquid air. Collie found that neon luminesces under the influence of the Hertzian waves. A tube of neon serves as a detector of the nodes and loops, glowing brilliantly under the influence of the latter, as if it were excited by an induction coil. Tubes of neon prepared by Claude thus excited offer a most pleasing and perhaps later on an economical form of artificial light.

"Quantities of argon are now available from liquefied air. There are indications that, on account of its inertness, we may shortly see tungsten incandescent lamps, as Whitney puts it, with the 'vacuum jam-full of argon' instead of nitrogen. Troost and Ouvrard have stated that they have succeeded in causing argon to combine with magnesium vapor. Neither Rayleigh, Ramsay, nor Moissan were able to secure any evidence of the formation of compounds of argon, however. Many reactions unobserved on the laboratory scale are found to occur when dealing with large quantities of substances, through long periods of time. If this were not true we should have even greater difficulty in accounting for the occurrence of such inert gases as helium in malacome, cleveite and thorianite. It is thus barely possible that in time we shall find compounds of argon produced in the large-scale operations of burning the nitrogen of the air, as carried on so successfully in Norway at present. A use of compounds of argon may then be found.

The development of radioactivity has projected us into an undreamed realm of thought and new interests. The phenomena of radiology are closely allied to those of radioactivity. The use of Roentgen rays in medicine has been attendant with not a few difficulties. Among them the so-called 'hardness' and 'softness' of the rays. The former are the penetrating and affect tissues, sometimes favorably and sometimes unfavorably far below the surface. The 'soft' rays affect the epidermis. In the use of 'hard' X-ray tubes for deep treatment, it is necessary to screen the skin with various thicknesses of aluminium, or lead, etc. For treatment of skin affections only there have been no satisfactory means for screening out the penetrating rays, consequently the problem has been the production of 'soft' rays with a minimum of 'hard' rays.

"X-ray tube glass is usually a potash or soda lime silicate. Lindemann found that by substituting lithium for potassium the rays were 'softer.' He then substituted beryllium for calcium, and finally boron for silicon. Lithium-beryllium-boron glass shows over 30 per cent reduction in the empirical molecular weight. Windows of this glass let into X-ray tubes give the 'soft' rays desired. One of these tubes wherein three 'unused' elements are utilized was exhibited through the courtesy of Waite & Bartlett. It would be interesting to try a potassium-barium-zirconium glass.

"In connection with the above I show you samples of titan-quartz and zircon-quartz glass, for which original properties are claimed. Analyses of such quartz published in the *Chemiker Zeitung* show from 0.05 to 0.15 per cent of zirconium and 0 to 0.11 per cent of titanium oxide, so they are what they are not.

"Application of the newer electronic conceptions of valence especially when associated with residual affinity with the development of methods for changing valence according to our wishes will unquestionably cause many of these unused elements and many of those now most used to assume new properties. I call your attention to one qualitative illustration. Pure lead does not plate on iron. When molten lead is caused to flow to and fro as a conductor of a low-voltage, high-amperage alternating-current for variable periods of time, usually several hours, it then plates iron as may be seen from the sample so plated this week. The lead is pitted and the sample not perfect, but it points a way which may serve as a hint in seeking uses for such elements as cadmium, selenium, and tellurium.

"An indifferent and unsatisfying classification of the 'unused' elements has been attempted. Over one-third are little used. 'Rare' elements have been shown not to be so rare. Furthermore, rarity bears little direct relationship to utility. Desire to eat the cake and keep it at the same time are important factors in making use of some of the elements. Illustrations of the development of methods for reducing the cost of production have been cited. Means for stimulating work in utilizing elements now available have been suggested. These workers at least could correct much of the misinformation now transmitted by the normal channels from one generation to another. Directions in which real modern physical chemistry has made it possible to use some of these elements and opened up further possibilities have been mentioned. The limited time and assumed patience of our members have forced a degree of unavoidable superficiality.

"These joint meetings and one leading paper remind me of Jerome Travers and his 'Three Men in a Boat.' I have realized from the beginning that the task set me by your three presiding conspirators was no mean one and might perplex even Montmorency. If the weaving of the potash and pearlmutterings of the 'Unused Elements' into a dramatic curtain raiser has not carried interest and profit, lay it not to a sigh which has not been sensitive to lights and shadows but to a memory unable to recall the visions."

### Cobalt and Cobalt Alloys

The first paper dealing with a special undeveloped element, namely, cobalt, was presented by Dr. **Herbert T. Kalmus**, of the School of Mining, Queen's University, Kingston, Ontario, who has devoted several years of work to the study of cobalt and cobalt alloys. In view of the interest of the subject we herewith give Dr. **Kalmus'** paper in full.

The cobalt-oxide industry is a very old one. It probably started, on what might be considered a commercial scale, at Schneeberg, Germany, in 1520; about this time "blue cobalt," cobalt smalt, from Schneeberg, was being sold at Venice. The smalt contained about 6 per cent of cobalt. The smalt industry had a very interesting history in Saxony and Bohemia during the sixteenth to eighteenth centuries, during which time it grew very rapidly. F. Kapff, Finance Minister of Prussia, made a report of the industry in 1792, in which he estimated that thirty smalt works were at that time putting out 3000 tons of smalt per year.

At the present time these German and Austrian mines are important for bismuth and radio-active materials, the silver and cobalt having become quite insignificant. The historical development of this German silver-cobalt district is interesting because it probably forecasts the history of the present Ontario silver-cobalt camp, in that the production of cobalt continued over a long period after the camp had been depleted of its silver values.

During later years up to 1904-05, New Caledonia, New South Wales, Chili, Spain, Norway and Prussia supplied the world with cobalt. The output of New Caledonia at the time the Ontario deposits were discovered was probably 85-90 per cent of the world's supply. In 1904, Mr. A. Glasser, "Report in 1904, to the Minister of the Colonies, on the Mineral Wealth of New Caledonia," stated that New Caledonia has practically the monopoly for the production of cobalt for the whole world. The ores were not smelted or refined in New Caledonia, but were shipped to Europe to be treated.

The silver-cobalt mines of Ontario began to produce in 1904, and since that time they have wrested the monopoly in the production of cobalt from New Caledonia. The price offered for the CoO content of New Caledonia ores, running 8 per cent in CoO, had fallen from about 85 cents per pound in 1904 to approximately 20 cents per pound in 1908.

In the Ontario silver-cobalt district the more important ores in the veins are, native silver, smaltite ($CoAs_2$), niccolite ($NiAs$), chloanthite ($NiAs_2$), associated with which are usually found some dyscrasite ($Ag_3Sb$), argentite ($Ag_2S$), pyrargyrite ($Ag_3SbS_3$), Cobalt bloom ($Co_3As_2O_8 + 8\,H_2O$) and nickel bloom ($Ni_3As_2O_8 + 8\,H_2O$).

The metallurgical treatment of these ores is more or less secret, but a brief account of the Canadian practice may be found in the report of Mr. Arthur A. Cole, mining engineer, Temiscaming & Northern Railway Commission, Toronto, 1913.

Until the last year about one-half the ore from the Cobalt camp found its way to United States smelters. The ore is silicious and mixes well with United States basic ores. So far as the writer is aware the cobalt content of the ore shipped to the United States has never been recovered to any extent. The present United States practice leaves it in the form of residues containing Pb, Cu, As, Sb, S, Ni, Fe, Ag, and Au; that is, in rather bad shape to be treated for cobalt.

Up until the last year or so practically the only way which cobalt found its way into the industries was as cobalt oxide, $Co_3O_4$, for use as blue coloring substance. During the last few years the production of cobalt from the Ontario mines much exceeded the consumption of cobalt as cobalt oxide. The writer reported,[1] January, 1913, that the cobalt oxide industry consumed about one-third of the present output of the camp. During the last year the demand for cobalt oxide has considerably increased so that although the cobalt output of the Ontario mines is still very much in excess of the consumption of the metal cobalt, it is no longer true to the degree stated above. A considerable amount of statistical work would be required to make a satisfactory estimate of the present cobalt output of the Ontario mines, but you may take 1000 tons of cobalt metal per year as a rough working estimate, in order to orient yourselves as to the general magnitude.

In the year 1911 the Mines Branch, Canada Department of Mines, arranged with the School of Mining, Queen's University, Kingston, for researches to be undertaken with the view of extending the commercial usages and economic importance of the metal cobalt. To this end this laboratory has been operating continuously during 1912-13, under the direction of the writer.

Researches have been and are being undertaken under the following subdivisions:

I. Preparation of metallic cobalt by reduction of the oxide.

II. A study of the physical properties of the metal cobalt.

III. Electroplating of cobalt and its alloys.

IV. Cobalt alloys of extreme hardness.

V. Cobalt alloys with non-corrosive properties.

VI. Cobalt steels.

The first of these papers is in press, the second is ready for press and the rest will follow during the coming year. The experimental work on all of them has been so nearly completed that they probably can be finished during the present year.

It is impossible at present to give out the details of these investigations in advance of their publication by the Department of Mines, Ottawa, even were it possible to do so in a brief paper; however, the following general statements may be made as a result of the investigations and experiments:

(1) The preparation of black cobalt oxide, $Co_3O_4$, from Ontario silver-cobalt ores, has been worked out and is at present extensively practised at the Canadian smelters; therefore, this oxide was taken as the raw material for these investigations.

(2) Metallic cobalt, of a very high degree of purity, may be made from this oxide by reduction with carbon, with carbon monoxide gas, with hydrogen gas, or with aluminium; the former three at such tempera-

---

[1] Summary Report of the Mines Branch of the Canada Department of Mines for the year 1912, p. 94.

tures as to make it commercially attractive and economical.

(3) Metallic cobalt is not so closely identical with nickel in its properties as has been commonly considered.

(4) Cobalt is considerably harder than nickel, being about 125 on the Brindell scale of hardness, whereas nickel is about 65 on the same scale.

(5) Cobalt up to about 15 per cent, alloyed with steel containing small percentages of chromium and tungsten or molybdenum, yields alloys of extreme hardness, and of very superior cutting qualities when used as high-speed tool steels. Nickel substituted for cobalt in these alloys does not in any case give the same results

(6) The melting point of pure cobalt we find to be 1467 deg. C., to within 5 deg., whereas that of nickel is 1435 deg. C. Therefore, so far as its melting point is concerned cobalt is not very much more difficult than nickel to alloy.

(7) Pure cobalt has a higher tensile and compressive strength than any of the pure metals with which the writer is familiar. The effect of cobalt on the tensile and compressive strength of certain alloys and steels is being studied.

(8) Cobalt is magnetic at all temperatures up to about 1100 deg. C. We have found an alloy of cobalt and iron, approximately $Fe_2Co$, which has a magnetic permeability in strong magnetic fields about 10 per cent higher than the best Swedish soft iron. This has been independently discovered at this laboratory and by P. Weiss, Zurich, Switzerland.

(9) Cobalt alloys with chromium and the resulting cochrome may be swaged to form wires, which are in some respects superior to nichrome wires as heating elements; they are less readily oxidized at high temperatures, and have a higher melting point. The thermo-electric properties of cochrome are being studied.

(10) Small percentages of cobalt added to pure iron give alloys which are extremely non-corrosive and which will probably find extended use as sheet roofing materials. These are at present being tested on a commercial scale.

(11) Cobalt when electroplated on steel and brass gives a more adhesive plate with a more silvery appearance than nickel. It seems to be less readily corroded than nickel under ordinary atmospheric conditions and upon handling.

(12) Cobalt will probably find extended use in the plating industries for special purposes, even at a much higher price than nickel, in that it may be plated with extreme satisfaction from a more concentrated solution than nickel, and at a much higher current density. Cobalt can be deposited several times as rapidly as nickel.

The details of these observations, with numerical constants and complete data, are being and will be published during the coming year by the Mines Branch, Canada Department of Mines, Ottawa, and this brief preliminary note is given with the permission of the Director of Mines.

* * *

Dr. Chandler, called upon to open the discussion referred to some specimens from the Columbia University Museum, exhibited on the lecture table, and spoke of a cobalt anode which he had used many years ago and which had been made at Wharton's shop.

Dr. Baskerville called attention to some samples from the museum of the College of the City of New York, also exhibited on the lecture table.

In reply to a question Dr. Kalmus said as to a comparison of cobalt and nickel plating that a far purer anode of cobalt than of nicked could be used. This is of importance, as Mr. Addicks explained, because on account of the iron contained in commercial nickel anodes the nickel plating deposit will contain iron and therefore be liable to rusting.

In reply to a question of Dr. Richards, Dr. Kalmus said that alloys of cobalt and nickel had not yet been investigated.

In reply to another question as to further comparative data concerning nichrome and cochrome wire, Dr. Kalmus said that these could not yet be given, because the amount of cochrome wire made so far was very small.

Mr. Addicks called attention to a newly developed cobalt deposit, that of Katanga copper in the Belgian Congo, containing 6 per cent Co and 1 per cent Fe.

Mr. Cowles gave some interesting data on early work on copper-cobalt and zinc-cobalt alloys.

The chairman, Mr. Addicks, then passed over to the subject of boron with the following remarks: "Boron represents another class—unbalanced development. It is a peculiar element standing almost alone on the dividing line between the metals and non-metals. The supply is enormous and there is a large consumption of borax and boric acid. Other boron compounds have very limited application and elemental boron was a chemical curiosity until Dr. Weintraub, of the General Electric Company, discovered a glorified application of the borax assay bead, in that boron will deoxidize copper without leaving a dissolved residue, which depresses the conductivity." He then introduced Dr. E. Weintraub.

### Boron

Dr. E. Weintraub, of the General Electric Company, West Lynn, Mass., distinguished three periods in the recent development of boron. The first relates to the isolation of boron, the second to the technical applications of boron, and the third to their commercial utilization. We are now well ahead in the third period.

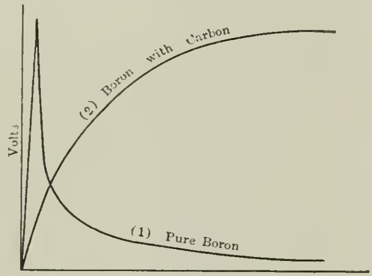
The main commercial uses of boron are based on its peculiar properties of high specific electric resistance and the negative temperature coefficient. The specific conductivity of boron of 0 deg. C. is about $6 \times 10^{-7}$ mhos per cm cube. This high-specific resistance of boron is accompanied by a negative temperature coefficient of resistance, which is also unprecedented among elements. The resistance of boron drops very markedly as the temperature is increased, and it does this with exceptional rapidity at ordinary room temperature. At this temperature the conductivity of boron doubles in value for every seventeen degrees centigrade.

The influence of addition of other elements dissolved in boron is no less interesting. This influence is of extraordinary magnitude so that even as small an amount as 0.1 per cent of carbon, for instance, will increase the conductivity of boron manifold. When 7 to 8 per cent of carbon are dissolved in boron the remarkable characteristics of boron disappear altogether and the material has a conductivity comparable to that of silicon or even carbon.

These peculiarities are best understood by considering the curve connecting the current and the voltage across a piece of boron. In such curves as shown in the diagram on page 186 the amperes are given as abscissas and the volts as ordinates. For a material with a negative temperature coefficient of resistance, such as boron, the curve is necessarily concave to the axis of abscissas.

In the adjoining diagram the curves are plotted not to scale, but simply to bring out the essential difference between pure boron and boron containing carbon. The curve (1) for pure boron shows a clearly developed maximum. That is, if the current passing through the piece of boron is gradually increased the voltage at the terminals of the piece of boron increases until it reaches a maximum; with further increases of current the voltage decreases. This property at once suggests the use of boron as a cut-out.

Dr. Weintraub expressed the belief that in such cut-outs boron will find a very large field of usefulness especially in connection with series lighting. Whenever the voltage rises beyond a certain value the boron cut-out which before had a very high resistance will break down and open a path for the current.



VOLT-AMPERE CURVES FOR BORON AND BORON-CARBON

If a little carbon is added to boron the nature of the volt-ampere curve changes and by adding more and more carbon the form of the curve (2) in the adjoining diagram may be obtained which reaches a maximum and then remains practically constant, becoming parallel to the ampere axis. Such boron-carbon resistors are practically applicable for voltage regulators. The principle is that if such a boron-carbon resistor is in shunt with a conductor to be regulated, and if the current fluctuates the boron-carbon conductor will absorb more or less current while the conductor in parallel maintains its amperes constant so that the voltage at the terminals remains constant. This property is made use of in car-lighting regulators.

Another type of boron-carbon resistors in an atmosphere of nitrogen (containing a little less carbon than the type just discussed) is employed for automobile lighting regulators to take care of the variations of speed. These regulators are placed in the field of the generator.

Dr. Weintraub finally discussed briefly the possible application of boron resistors as electric thermometers. On account of the great temperature coefficient they should be particularly applicable for such a purpose. The main difficulty has been to make reliable contacts with boron. This difficulty has been bad enough in connection with cut-outs and regulators but has there been completely overcome. On the other hand, this difficulty is much greater with thermometers as in this case the contacts must be absolutely constant. However, Dr. Weintraub concluded that he believed they were now at the end of the difficulties even in this case.

### Ductile Tungsten

Dr. R. W. Moore, of the General Electric Company, of Schenectady, N. Y., remarked in his paper on ductile tungsten that probably no other element has had such a rapid rise from comparative obscurity to great industrial importance as tungsten since the development of a process of rendering this hitherto extremely brittle metal ductile. Tungsten is by no means a rare element. The two chief minerals are scheelite (tungstate of calcium) and wolframite (tungstate of iron and manganese).

Scheelite is readily broken up with hydrochloric acid, forming calcium chloride, and leaving the tungstic acid mixed with the various insoluble portions of the ore (mostly silica). The tungstic acid may be dissolved in ammonia or caustic alkali and the solution then precipitated with acid to give the crude tungstic acid, $WO_3$.

Wolframite is most readily broken up by fusion with an alkali flux (caustic soda or carbonate) extracting the alkali tungstate with water and precipitating the tungstic acid as before. This crude oxide, roughly reduced with carbon, is the product used by the steel industry and is the metal that sells for approximately a dollar a pound.

But for the metal that is to be used for making ductile tungsten, this oxide contains too much impurity. The impurities vary with the ore, but the main ones are Fe, Mn, $SiO_2$, Ca, Mo, P, As, and Na salts. Two methods of purification are in general use:

First, solution in ammonia and crystallization of para ammonium tungstate. This is washed, dried and broken up by heat,

Second, solution in ammonia and precipitation of tungstic acid with hydrochloric acid.

A third method which is used where still greater purity is desired is a combination of the other two, i.e., crystallization and then the decomposition of the crystals with aqua regia.

The first method removes a large portion of all the impurities, but gives a heavy dense oxide from which it is more difficult to get a metal of satisfactory qualities.

The second method gives an oxide purer from some impurities than the crystallation method, but does not remove the P, and As at all completely; these, however, come out later in the process of working the metal. This oxide is light and readily reduced.

Two methods of reduction are being used, one with carbon and the other with hydrogen. By far the greater proportion of the metal used is hydrogen-reduced. Reduction by carbon is much less readily controlled, since under certain conditions the carbon may burn either to CO or $CO_2$; also some of the lower oxides of tungsten are volatile at fairly low temperatures. The finished metal must contain practically no carbon and practically no oxygen; also the density of the metal must not vary much from a certain standard, and it must not be crystalline. To realize all these conditions is somewhat difficult, but this method is in successful use.

The reduction with hydrogen is more readily controlled and is the process generally used. The oxide is reduced in electric resistance furnaces, with the temperature and rate of hydrogen-flow under careful control. The furnaces used are of two different types: First, porcelain tubes wound with platinum ribbon embedded in an insulating material either alumina or silica, and second, furnaces of the Winne and Dantsizen type, employing alundum tubes wound with tungsten or molybdenum wire, embedded in insulating material, contained in tight casings through which hydrogen is flowing to prevent oxidation of the winding. Each type of furnace has its advantages.

The oxide is loaded into the furnaces, either in boats, or directly into the tubes, purified and dried hydrogen passed through, and the temperature brought gradually up to about 1000° to 1100°. The rate of heating and the rate of hydrogen-flow largely determine the quality of the metal. This reduction process gives a completely reduced metal, without any crystalline structure; the density of the metal is under control and variable at will within the limits.

The tungsten thus produced is a dull-gray amorphous powder. The process of working this powder into a dough, ductile metal is radically different from any in use with other metals (except Mo).

Tungsten melts at about 3200°C. Even in spite of its extremely high melting-point, it is possible to form melted globules of tungsten of considerable size by means of a vacuum arc furnace. But tungsten that has been melted is extremely brittle and a globule of it when struck with a hammer flies into pieces like glass. It is impossible, at least, as yet to work pieces of tungsten which have been melted. Hence other methods of getting the tungsten into wire-form had to be worked out.

In the early days of the tungsten lamp, the tungsten powder was always mixed with some binder, either organic, like starch and the various gums, or metallic, such as some of the amalgams. The mixture was then squirted under pressure through dies, and the binder subsequently removed. Wire made by these methods was extremely brittle and fragile.

Since the process of making *drawn* tungsten wire was developed, practically all wire and other forms of ductile tungsten are made by the following process.

The dry tungsten powder, without binder of any form, is placed in a very heavy mold, care being taken that the powder is evenly distributed in the mold. The metal is then pressed into a bar by heavy pressure in a hydraulic press. This pressed rod has very little strength. It is carefully pushed from the surface of the mold into a slab of some material (usually molybdenum) and then placed in a furnace, usually of the Winne and Dantsizen type, heated to about 1300°. A current of hydrogen is passed through the tube to prevent oxidation. The bar is heated for about half an hour and then pushed out into a water-cooled extension of the furnace. This heating has sintered the metal so that the bar has sufficient strength to be readily handled without fear of breakage.

This bar is now clamped between two heavy water-cooled clamps, and a water-cooled cover or treating-bottle as it is called, is lowered over the whole. A current of dry hydrogen is passed through the bottle, and the bar then heated gradually up to a dazzling white heat—in fact nearly to its melting-point, by passing current through it. After a few minutes at this temperature the current is gradually turned off (to prevent air sucking back into the bottle and causing an explosion) and the bar allowed to cool. The tungsten is now thoroughly sintered and the bar is very strong—but as yet it has no ductility whatever.

From this point on, the treatment of the bars varies slightly, according to the use to which the metal is to be put. Sometimes the metal is rolled—sometimes swaged. The process in general is this: The bar is placed in an electric resistance furnace through which hydrogen is flowing, and heated to about 1500° C. (till it smokes in the air). It is then grasped with tongs and inserted rapidly into a swaging machine and then quickly withdrawn. It is reheated, and the other end passed into the machine. Care must be taken that the rod is passed rapidly into and out of the machine, so that it is not cooled too much.

The size of the dies is gradually decreased—several dies are used in bringing the rod from a square to a circular form. As the rod becomes smaller, the steps between the dies gradually become smaller and smaller, the temperature is gradually decreased, and when the rod is long enough it is fed through the machine mechanically by rolls, being drawn through a gas furnace or gas flame to heat it. When the diameter has been reduced to about 30 mils, the wire becomes ductile at ordinary temperature.

From this size, down to the smallest diameter the wire is drawn through diamond dies, first quite hot (600° to 650°) with a gradually decreasing temperature as the wire becomes smaller. The steps between the dies are gradually decreased from one mil at thirty mils to one-twentieth of a mil at fourteen mils and below. Wire as fine as one-half mil has been successfully drawn.

When not desired in the form of a wire, the treated bars are often rolled instead of swaged; sometimes both processes are combined. The metal is rolled hot in a manner similar to that used in swaging. From the rolled bars and sheets, various articles are made, such as contacts for electric apparatus of various kinds, X-ray targets, etc.

Tungsten is too hard to work on a lathe, or to be machined with tools. Hence other methods have to be used to get tungsten into any desired form. The metal sheets or bars are heated very hot, and then the desired pieces sheared, punched or forged out.

The properties of wrought or ductile tungsten are interesting. It is pliable, strong and tough. It is practically non-oxidized in damp air, and it resists acids to an unusual degree. It is unattacked by HF, only slightly attacked by HCl, $HNO_3$ or $H_2SO_4$ of any concentration hot or cold, or by aqua regia. Alkali solutions do not attack the metal, but fused alkalis dissolve it slowly. A mixture of $HNO_3$ and HF dissolve the metal rapidly. The specific gravity of tungsten is about 19.3. Its tensile strength is exceedingly high-samples of one-thousandth of an inch diameter have been obtained with a tensile strength of 600,000 to 650,000 lb. per sq. in. (several times that of steel).

The most important use for tungsten is, of course, as a filament for incandescent lamps. It is also being extensively used as a contact material where an electric circuit has to be made and broken repeatedly in the air, as in magnetos, etc., on automobiles, and in voltage regulators. Considerable use is being made of tungsten as a target in X-ray tubes, where it is being found exceedingly valuable. Tubes of tungsten are made and used as the heating unit in a furnace, in which a temperature of 2500°-2700° can be obtained in about five minutes, starting at room temperature. The furnace can be cooled and opened in about ten minutes, hence such a furnace is of the highest value in experimental work at high temperatures. The furnace can be filled with hydrogen or used as a vacuum furnace as desired.

A further use of tungsten is as a heater-winding for resistance furnaces such as the Winne and Dantsizen type and others. The temperature at which these furnaces can be run is limited at present only by the temperature which the tube or support on which it is wound will stand.

### Selenium, Tellurium, Cadmium

The chairman, Mr. Addicks, remarked that "selenium, tellurium and cadmium are three sad cases. The supply is fair and the consumption very small. Of course, they are used in medicine to a certain extent, but a doctor will use anything. The prescription of one of the fifteenth century physicians for the cure of fever began, after discussing the position of the stars: One heats in a brass pan 1½ oz. turpentine of cyprus and then introduce fifteen live spiders and mixes until the spiders have disappeared.

"Selenium has the property of imparting to the perspiration its characteristic odor, which is stated in the chemistries to resemble rotten radishes. It has been said that physicians find it an excellent ingredient for prescriptions where the patient is suffering from overwork and insists on going out to dances. . . ."

There was an interesting exhibit of several products of colored glass of the Corning Glass Works, of Corning, N. Y. In some interesting notes contributed by Mr. E. C. Sullivan it was stated that selenium produces a ruby glass much more satisfactory in transmission than any other ruby and they are using several thousand pounds yearly in the manufacture of such glass. Selenium, is recommended also for use as a decolorizer as it gives in small quantity a pink color which is complementary to the green color caused by iron.

With regard to cadmium sulphide they are using a few tons of this material annually to produce yellow color.

This company makes lantern globes and roundels for railway signal purposes, the red being obtained with selenium and the yellow with cadmium sulphide. Mr. Sullivan remarked that they were always interested in the less common elements since a decrease in price might make available for their use materials which are otherwise out of the question. Lithia and bismuth are possibilities along this line which suggest themselves at the moment.

In view of the late hour there was a comparatively brief discussion. Mr. J. B. F. Herreshoff spoke of the behaviour of selenium in the smelting and refining of copper and emphasized the influence of small quantities of foreign elements in copper on its electric conductivity.

After the close of the meeting the numerous exhibits on the lecture table were inspected with great interest by the audience. Besides the exhibits from the museums of the College of the City of New York and of Columbia University and of the Corning Glass Works there was also an interesting exhibit by Messrs. Eimer and Amend in charge of Mr. Childs. The whole evening was very enjoyable.

## An Apparatus for Making the Flash and Fire Tests of Lubricating Oils

BY H. L. SIEVER

By flash test we understand that temperature to which an oil must be heated to give off vapors, which when mixed with air produce an explosive mixture, while the fire test of an oil is the temperature at which it will give off vapors, which when ignited will burn continuously.

The latter temperature being obtained by continuing to heat the oil after the flash test is made.

Oils with a high flash point, such as lubricating oils, are as a rule made in an open cup or crucible, heated by a Terrill burner in an air or a sand bath.

The results obtained by making these tests in an open crucible are not always satisfactory.

There are several things to be considered when using a crucible, such as the quantity of oil, size of crucible, rate of heating, distance, and size of flame, draughts, etc., in fact unless these tests are made quite frequently one often forgets the exact conditions under which the previous tests were made. Porcelain crucibles are usually used for this purpose, but at high temperatures they often break, causing trouble, delay and expense. The accompanying illustration gives the dimensions for making a tester of machine steel which has proved to be very reliable and convenient in determining these temperatures.

It can be made of any cheap iron or steel at a small cost, and will last almost indefinitely.

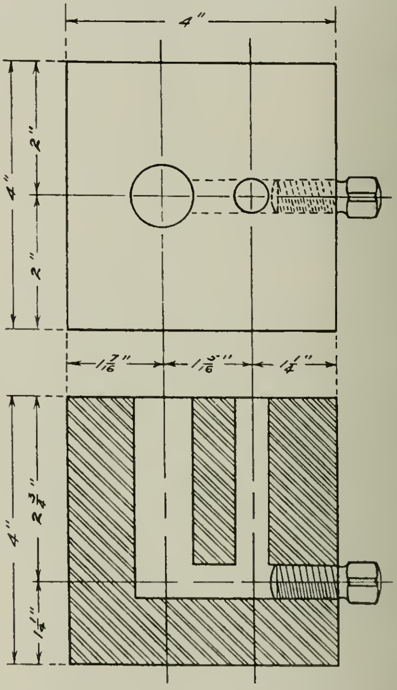
The advantages of this over an open crucible and sand bath are obvious. The most important being the volume of oil, which is the same for all tests, while the thermometer is entirely removed from the larger portion of oil where the test is to be made.

In practice this is placed on an ordinary iron support with a clamp for holding a thermometer.

Pour 35 c.c. of the oil to be tested in the large ⅞-inch hole and insert the thermometer in the small ½-inch hole, apply a fairly hot flame from a Terrill burner as near the center as possible.

The testing flame should be very small and applied at the edge or drawn across the top.

With this apparatus it is possible to accurately determine these temperatures to within one-half a degree.



SKETCH OF TEST ARRANGEMENT

By removing a set-screw with a pair of pliers the hot oil may be drawn off and arrangements made for a new test in a few minutes.

Laboratory, Morse Twist Drill & Machine Co.,
New Bedford, Mass.

**Preliminary statistics** of the value of metal production in the western states for 1913 have been given out by the Geological Survey: Alaska, $18,900,000, a decrease from 1912 of about $4,000,000; Arizona, $71,000,000 which is record output and an increase of 6 per cent; Colorado, $36,000,000 gold and zinc having decreased and silver, copper and lead increased; Idaho, $23,500,000, which is a record for that state and an increase of nearly 10 per cent; Montana, $59,000,000, a decrease of about half a million dollars, gold and copper having decreased while zinc made a record yield; Nevada, $36,374,000, a decrease of about 5 per cent, gold and lead having fallen off while silver, copper and zinc gained; New Mexico $11,600,000, an increase of $3,000,000, due mostly to copper; South Dakota, $7,200,000; Utah, $43,000,000, a slight increase. The production of coal, iron ore and petroleum broke all records, amounting respectively to 575,000,000 short tons, 58,000,000 long tons and 240,000,000 barrels.

# Mining Engineers' New York Convention

## Report of the Annual Meeting of the American Institute of Mining Engineers, Held in February in New York City

The annual meeting of the American Institute of Mining Engineers held in New York City from February 16 to 19 was a most enjoyable affair and was very well attended.

On Monday night there was a reception at the Institute's headquarters, opened by an address of welcome by President Charles F. Rand, and followed by a "mining-colored" smoker in which the humorous home talent of the Institute shone brilliantly.

The annual business meeting was held on Tuesday morning, when the results of the election of officers were announced. The number of ballots cast was 949.

Mr. Benjamin B. Thayer, president of the Anaconda Copper Mining Co., is the new president.

Messrs. H. C. Hoover and W. L. Saunders were elected vice-presidents and directors, and Messrs. R. W. Brock, D. C. Jackling, A. L. Ledoux, C. W. Merrill and Henry Smith, directors.

On Tuesday evening a meeting was held in the Museum of Natural History, at which the chairman of the New York section, Mr. L. B. Huntoon, presided. Mr. H. W. DuBois presented a beautifully illustrated lecture on "Placer Mining in British Columbia." The new model of the Copper Queen Mine, prepared with extreme accuracy and a gift of Dr. James Douglas to the Museum, was on exhibition. Dr. E. O. Hovey outlined the history and geology of the district, and Prof. James F. Kemp gave an appreciative sketch of the life and work of Dr. Douglas.

On Wednesday evening a subscription dinner at the Waldorf-Astoria was attended by some 200 members with their ladies. Mr. W. L. Saunders acted as toastmaster. Among the speeches, one by Senator Clark was particularly enjoyed. The banquet was preceded by a reception to the newly elected president, Mr. Thayer and the retiring president, Mr. Rand, and at the close of the dinner Mr. Rand introduced Mr. Thayer as the new president.

The professional sessions devoted to the reading and discussion of papers were well attended and extraordinarily successful. The scheme to give the different sections of the Institute a free hand in preparing the program and procuring papers proves very effective. During the last two days the program was so crowded that it was necessary to hold simultaneous sessions in two different rooms.

### Tuesday Morning Session

During the Tuesday morning session, which followed the annual business meeting, Mr. Spilsbury presided.

A paper by H. A. Guess on "Mining and Mining Methods in the Southeastern Missouri Disseminated Lead District," and a paper by James Johnston on "The Mill and Metallurgical Practice of the Nipissing Mining Co., Ltd., at Cobalt, Ontario," were presented in abstract by Mr. Robinson, in the absence of the authors. In view of the great metallurgical interest of the latter paper, we herewith give an abstract of the same:

### Nipissing Mill and Metallurgical Practice

At this mill a remarkably complex silver ore, averaging 54 oz. of silver per ton (run of mine ore) is treated to give a 95.66 per cent. extraction. Mr. Johnston points out that the main features of the processes are:

The cyanide amalgamation of the high-grade ore.

The cyanide treatment of the low-grade ore, after extremely fine grinding and close classification, in a caustic soda solution.

The use of a wet desulphurizing process to break up refractory silver minerals.

The substitution of aluminium dust for zinc dust as a precipitant.

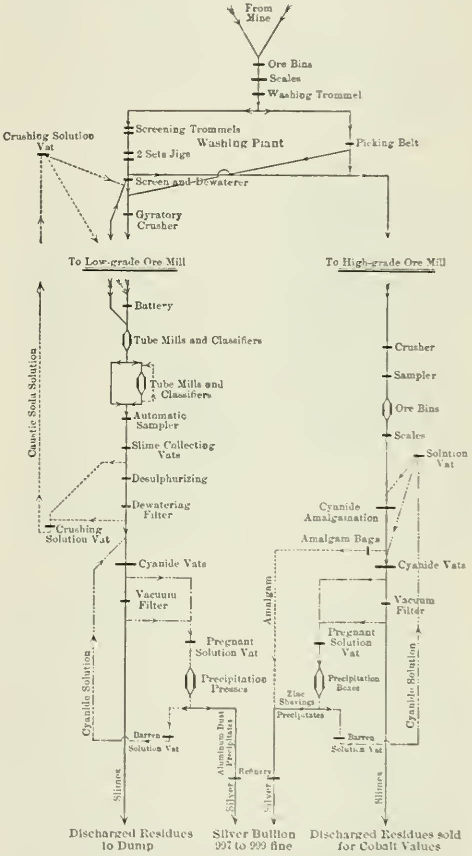


FIG. 1—FLOW SHEET OF NIPISSING MINING COMPANY'S MILL

The recovery and shipment of over 13,000,000 oz. of silver in bullion at 997 to 999 fine since this metallurgy was inaugurated, about 2.5 years ago.

After a review of the experimental work which preceded the design of the mill by Mr. Charles Butters and the author, the present mill practice is summed up as follows:

Crushing the ore to 3 in. in gyratory crushers before sending it to washing plant.

Hand picking and jigging of the high-grade ore in the washing plant, which is then sent to the high-grade ore mill.

Discards from washing plant, known as low-grade ore, crushed to 1.5-in. mesh and sent to battery.

Crushing in battery and tube mills in a caustic soda solution to all slimes.

Collecting slimes and desulphurizing in tube mill and vat.

Dewatering slimes and transferring to vats for cyanide treatment.

Filtering slimes and discharging to waste dump.

Cyanide solution from slime treatment vats and filters going to aluminium dust precipitation.

Aluminium dust precipitate taken to refinery, malted, and refined to silver bullion at 997 and 999 fine.

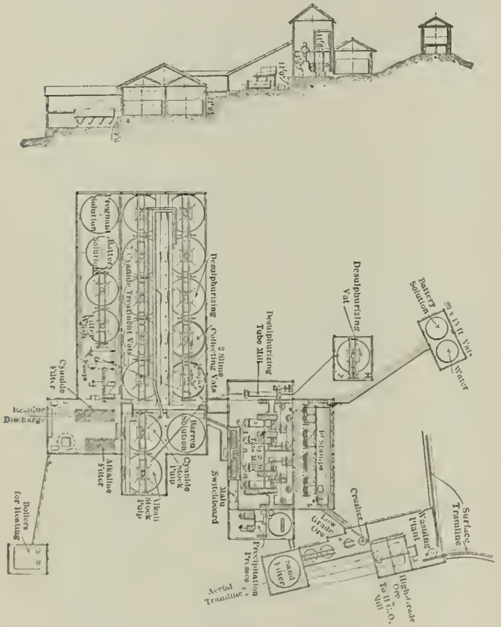

FIG. 2—PLAN AND SECTION OF THE LOW-GRADE ORE MILL OF THE NIPISSING MINING COMPANY

The flow sheet of the process is shown in Fig. 1, and the low-grade ore mill is shown in plan and section in Fig. 2.

Descriptions, with data on cost of erection, are given in the paper, of the foundations, the mill building, the washing plant, the battery, the tube mills, tonnage and values, launders, and the cyanide plant. The latter is placed in a building apart, but connected to the battery and tube mill building. It is arranged in two floors, the upper one containing all the slime collecting and the cyanide treatment vats and the lower floor containing all the solution vats, slime filters and pumps.

The desulphurizing process is an important novel feature of the process, so we give that portion of the paper which deals with it practically in full.

### DESULPHURIZING PROCESS

The problem of working out a successful all-cyanide treatment for Cobalt ores, in which there is such a varying amount of complex minerals, led to the discovery, during the period of experimental work, of what is now known as a wet desulphurizing process. Briefly explained, the preliminary desulphurizing treatment breaks up the refractory silver minerals when the slime pulp is brought into contact with aluminium in a caustic soda solution, the silver being left in a spongy metallic state readily amenable to cyanide treatment.

The desulphurizing is accomplished by passing the slime pulp through a revolving tube mill, in which there is a quantity of aluminium, and a further treatment is given in a vat lined with aluminium plates, in which the pulp is slowly agitated.

The practical effects of this preliminary treatment on the ores has resulted in the same and sometimes a better extraction being obtained in 48-hr. cyanide treatment than was otherwise obtained in 120-hr. cyanide treatment with no desulphurizing. In some of the ores which contained a greater proportion of the refractory minerals a better extraction of from 1 to 4 oz. per ton is obtained when desulphurized and cyanided, as compared with a cyanide treatment and no desulphurizing.

A tube mill, 4 ft. in diameter by 25 ft. long, lined with 2-in. thick Silex blocks, is used for the first stage of the desulphurizing treatment. This mill revolves at 10 revolutions per minute and carries a load of about 4000 lb. of aluminium ingots, cut up into cubes about 1.5 to 2 in. The slime pulp is fed through this mill at the rate of 14 tons of dry slimes per hour, diluted with 1.5 caustic soda solution to 1 dry slime. The pulp then gravitates into the 34-ft. diameter by 13-ft. deep alkali stock pulp vat, which is arranged with mechanical agitation and lined around the side with aluminium plates. The pulp is agitated in this vat about 24 to 36 hr., or until it is gradually drawn off in about 40-ton charges to the dewatering filter box. On account of keeping the mill cyanide solution in balance, it is necessary to eliminate as much as possible the crushing caustic soda solution from the slimes before they are transferred into the cyanide vats for treatment, and this is done in a Butters filter plant equipped with 60 leaves, which is capable of dewatering 270 tons of slimes per day, the cake when discharged carrying 26 per cent. alkali solution as moisture.

The slimes after dewatering flow into a 16 ft. by 5 ft. deep pulping vat, where they first come in contact with cyanide solution, being diluted with about 2 of cyanide solution to 1 of slime, a 4 in. diameter centrifugal pump being used for transferring the pulp into the cyanide treatment vats.

### CYANIDE DEPARTMENT

There are seven 34-ft. diameter by 13 ft. deep slime treatment vats, fitted with mechanical stirring arrangement. Each vat has a 6-in. diameter decanter, for draining off the clear settled cyanide solution they are also fitted with a 6-in. diameter air lift operated by 0.75-in. diameter pipe with air at 20 lb. pressure.

The slimes are treated in charges of about 130 tons dry slimes in a vat with a dilution of 2 of solution to 1 of dry slimes in a 0.25 per cent cyanide solution and 0.20 per cent alkali, agitation being maintained for 48 to 60 hr. Repeated testing in the mill has demonstrated that equally as good an extraction of the silver values is obtained with a 2 to 1 dilution as with a 3 to 1 dilution. The air lift is operated all the time the charge is being treated, so that there is a possible turning over of the charge about 16 times by the air lift.

After the agitation treatment, the charge is allowed to settle, so that the clear solution may be decanted to the pregnant solution vat. The pulp is then agitated and transferred by a 7-in. diameter centrifugal pump to the 34-ft. diameter by 13-ft. deep cyanide stock pulp vat, in which it is kept agitated until drawn off into the filter box.

A Butters filter plant equipped with 80 leaves handles 35 to 40-ton charges in about 3 hr. each, the slimes being discharged with 26 per cent of moisture. The alkali and the cyanide filters are arranged alongside of each other so that the same operator handles both boxes from the switchboard placed between them. The filter plants are arranged on the semi-gravity plan; a 10-in. diameter centrifugal pump with 12-in. diameter suction and delivery pipes and hydraulically operated valves is connected with the cyanide box for transferring the excess pulp and solution wash. The clear solution from the cyanide filter box is delivered to the pregnant solution vat and the residue slime is dropped into the empty box, discharging by gravity to the residue dump.

The alkali filter box is connected to an 8 by 10-in. duplex double-acting piston vacuum pump with a displacement of 340 ft. per minute at 160 revolutions per minute. The cyanide box has a 12-in. diameter by 10-in. stroke duplex double-acting piston vacuum pump with a displacement of 770 ft. per minute at 160 rev. per minute.

The pregnant solution vat is 34 ft. diameter by 8 ft. deep and the barren solution vat is 34 ft. diameter by 13 ft. deep.

### PRECIPITATION DEPARTMENT

The original plans of this section of the mill were laid out with the intention of using zinc dust for precipitation and an equipment was installed of one 20-frame and one 10-frame 52-in. Merrill precipitation presses with 3-in. frames, together with the other necessary machinery.

Before the mill was ready to start, the experimental work on the use of zinc dust as a precipitant had disclosed that the cyanide solutions after precipitation rapidly deteriorated and fouled, so as to lose their dissolving efficiency. After considering various other methods of precipitation, it was decided to use aluminium dust as the precipitant and modify the equipment accordingly.

The practical benefits gained by this change are:

No fouling of cyanide solutions, with a corresponding reduction in dissolving efficiency.

The working mill cyanide solutions are in a more active condition to dissolve silver than if they were freshly made up solutions which had not yet been used, showing in their favor an increased dissolving power of 0.35 oz. of silver per ton of ore.

A regeneration of 0.608 lb. of cyanide per ton of solution precipitated, equal to about 1.67 lb. of cyanide per ton of ore treated, or 408 lb. per day.

The recovery of silver precipitates averaging about 27,000 oz. per ton, or about 93 per cent silver.

The pregnant solution is pumped to the precipitation room by a 6 by 9-in. vertical triplex pump, running at 54 strokes per minute, where it is clarified in a sand filter before flowing to the special tank arrangement for mixing the aluminium dust in the cyanide solution. It is then pumped into the precipitation presses by another 6 by 9-in. vertical triplex pump. The 20-frame press takes about four days to fill up with precipitates when handling about 550 to 600 tons of solution per day with a head assay running about 8.25 oz. and a tail assay 0.10 oz. The aluminium dust consumption over a nine months' period averages about 0.556 lb. per ton of ore treated, or 1 lb. (avoir.) dust = 45.26 oz. (troy) silver precipitated, or 1 lb. (avoir.) dust ≐ 3.104 lb. (avoir.) silver precipitated. The precipitates are sent to the refinery, where they are melted and refined in a reverberatory furnace, as described in R. B. Watson's article, and eventually shipped as bullion at 997 to 999 fine.

A heating plant is provided which maintains an average temperature of about 60 deg. F. in the coldest weather, which is sometimes down to 40 deg. below.

The paper (which is published in full in the January issue of the *Bulletin* of the Institute) is concluded by figures of extraction, operating costs, and electric power.

In the discussion which followed, Mr. T. T. Read, emphasized how much valuable research work is now being carried out in this country. Mr. Spilsbury called attention to the high extraction obtained in comparison with the Mexican practice. Mr. Packard spoke on early pioneer work in Utah and Montana in the cyaniding of silver ores. Mr. Chauvenet attributed the recent big advances in cyaniding to two causes, namely, fine grading and the slime filter. Mr. Hore sketched the advances made at Cobalt in low-grade ore treatment.

### Tuesday Afternoon Session

During the afternoon session, at which Mr. Wm. Kelly presided, the chief subject of discussion was the use of electricity in mines. The program of the afternoon session was as follows:

Use of Electricity at the Penn and Republic Iron Mines, Michigan, by Wm. Kelly and F. H. Armstrong.

The Application of Electric Motors to Shovels, by H. W. Rogers.

Remarks on Electric Traction in Mines, by Charles Le Grand.

Safeguarding the Use of Electricity in Mines, by H. H. Clark.

The Safety of Underground Electrical Installations, by C. M. Means.

The Injection of Cement Grout into Water-Bearing Fissures, by Francis Donaldson.

Drilling Performances at the Kensico Dam, Catskill Aqueduct System, New York, by W. L. Saunders.

The Work of Crushing, by Arthur F. Taggart.

### Wednesday's Sessions on Iron and Steel

Papers on iron and steel were presented in the two sessions on Wednesday. Dr. A. Sauveur presided at the morning session, and Dr. J. W. Richards at the afternoon session.

The first paper, by **H. M. Howe** and **A. J. Levy**, on the plastic deformation of steel during overstrain, was presented by Professor Howe. The subject was discussed on the basis of a fine series of microphotographs, shown by lantern slides. The paper was discussed by Professor Carpenter, of London, and Messrs. Hibbard, Webster, Sweetser, Lindgren and Howe. There was an enjoyable exchange of international pleasantries between Professor Carpenter on one hand and Dr. Sauveur and Professor Howe on the other.

A paper by **Albert Sauveur** on some heating and cooling curves of Carpenter's electrolytic iron followed. Dr. Sauveur concluded that the existence of A2 in pure iron as an independent point is no longer a debatable question. Whether this point is or is not an allotropic point appears to depend upon our conception of allotropy. The paper was briefly discussed by Professors Carpenter and Howe.

Two papers presented during the morning session dealt with manganese steel. A paper by **B. Hopkinson** and **Sir Robert Hadfield** on a research with regard to the non-magnetic and magnetic conditions of manganese steel was presented in abstract by Dr. Richards and discussed by Messrs. Potter, Howe and Sauveur.

A paper by **W. S. Potter** on manganese steel with special reference to the relation of physical properties to microstructure and critical ranges was presented by Mr. Potter. He showed a very long series of lantern slides and was complimented by Dr. Sauveur on the vast amount of information contained in the paper.

### Oxygen in Cast Iron

The paper by Mr. **J. E. Johnson, Jr.,** on the influence on quality of cast iron exerted by oxygen, nitrogen and some other elements, proved the most sensational and most debated paper perhaps of the whole meeting. The paper is printed in full in the January issue of the *Bulletin* of the Institute. We give here only an abstract of the paper with such information as was given by Mr. Johnson at the meeting on more recent developments.

Mr. Johnson's argument is as follows: Ordinary chemical control does not determine completely the quality of iron. Certain irons of apparently the same chemical composition, as determined by ordinary analysis, have different qualities, structure, strength, etc. These qualities are preserved on remelting and reappear in castings of which these irons form an important ingredient. The explanation cannot be found in the rarer elements, such as nickel, cobalt, chromium, titanium, vanadium and the like. All this is proven by a great deal of experimental evidence.

As it seemed inconceivable that a quality which would survive remelting and superheating to a point well above the fusion point, as in foundry practice, should be a purely physical quality, the explanation was sought in the common gaseous elements, oxygen, nitrogen and hydrogen. Mr. Johnson claims to have found the explanation in the oxygen content.

Mr. Johnson discusses the content of oxygen in coke irons and in charcoal irons and gives the results of tests proving the following two facts:

First, strong, tough irons of high chilling qualities contain oxygen in appreciable quantities. Weaker irons of similar analysis contain less or no oxygen.

Second, poor and normal irons may be improved beyond recognition by introducing oxygen into them.

As to the conditions in which the oxygen exists nothing is known. "We have been unable to detect it with the microscope, and we can only assume that it is some oxide of very much lower degree than any with which we are familiar."

Its effects seem to be two-fold:

First, it makes the iron very much more sensitive to chilling influences. One of these good irons if cooled normally will be only slightly harder than a normal iron, and on account of its fine, close grain will machine beautifully, but if the surface be chilled even slightly it begins to whiten up, and with a chill of any strength will be solid white at the edge, where a normal iron of the same silicon would show little chill, or none at all.

Second, the other principal effect consists in the extremely fine subdivision of the graphite in the strong irons, contrasting conspicuously with the large, coarse aggregates of graphite in the weak irons.

This was clearly shown by Mr. Johnson at the meeting in a series of microphotographs. These were shown in pairs. The two irons of the same pair had the same chemical composition, with exception of the oxygen. The two structures shown side by side showed clearly the large, coarse, aggregates of graphite in the low-oxygen iron (weak iron) and the finely subdivided graphite in the high-oxygen iron (strong iron).

A further condition which exists in these high-oxygen irons is that the tendency to form plates of eutectic and to form a spot in the center of the pig is entirely suppressed, no matter what the silicon of the iron may be, even with quite high carbons.

The subject is further discussed by Mr. Johnson under the following headings: Comparison of high-oxygen cast iron and malleable cast iron; reason for low-oxygen content ordinarily; condition for high-oxygen content; coke-furnace conditions as regards oxygen, the effect of different types of heat balance on quality of iron high versus low carbon; the effect of other elements (nitrogen, cyanogen, phosphorus, chromium, manganese), and the reason for the poor quality of manganese and chrome chills.

Mr. Johnson's final conclusions are summed up as follows:

"1. Irons which contain oxygen to a considerable extent, in a form as yet unknown, are stronger and tougher and have better chilling qualities than irons containing less of this element, but of the same analysis in other respects.

"2. Irons may contain a sufficient quantity of carbon to make them rotten and worthless through the predominance of the eutectic structure when deficient in oxygen, and yet, when they contain a considerable quantity of oxygen, be entirely free from this structure and of excellent quality.

"3. Furnace conditions control whether the carbon shall be below or above the eutectic ratio and the presence of much or little oxygen, the two dominant factors in the fundamental quality of the iron; that iron, broadly, being the best which is made at the lowest temperature.

"4. Charcoal irons can be made at temperatures several hundred degrees lower than are practicable with coke and have a great possible advantage in that respect. This is largely wasted without good furnace work in the broadest sense.

"5. Phosphorus up to 0.50 per cent or more exercises a beneficial influence on the strength of the iron and the depth and character of the chill. Phosphorus also has a tendency to reduce total carbon.

"6. Aluminium and titanium tend to reduce the strength and chilling power of the iron by removing its oxygen, but titanium may have an influence independent of this on account of its removing nitrogen also.

"7. Chromium and manganese have an almost identical effect in raising the total carbon and throwing it into the combined condition. The latter increases the chill and the strength, but the combined carbon so produced is in the form of eutectic plates, which deprive the iron of much of the strength which it would have with the same combined carbon in the absence of these plates.

"8. Chill produced by these elements cannot be expected to have the same wearing qualities as that produced by elements which do not further the formation of flat plates of eutectic."

The paper elicited a long and lively discussion.

Dr. Moldenke said that while he agreed with much that is in Mr. Johnson's paper, yet he could not accept his main conclusion that oxygen is beneficial.

Professor Howe pointed out that according to Mr. Johnson, not the oxygen itself but the resulting reduction of the graphite from large flakes to smaller particles is the really beneficial element.

Mr. Stoughton defended Mr. Johnson against the attacks of Dr. Moldenke. It is simply claimed that the irons with more oxygen content have a better structure. The oxygen may have an influence in throwing the eutectic point to the right, though there is no direct evidence for this statement.

Professor Campbell suggested a way how the oxygen may affect the method of throwing out the graphite—which is so important for the final structure.

After Messrs. Hibbard, Stoughton and Sweetser had discussed the existence or non-existence of such a thing as good iron that makes bad steel, and Mr. John Howe had called attention to some new test results not yet given in Mr. Johnson's printed paper, but confirming his claims, Dr. Moldenke reiterated his conviction that oxygen in cast iron cannot be beneficial. This, he said, was not theory, but the result of his foundry practice of many years.

In his final reply Mr. Johnson referred to some experiments made recently by him with the object of converting ordinary coke iron into iron of a grade equal or superior to charcoal iron. These experiments have been exceedingly successful. He took an ordinary iron of about 1 per cent silicon and cast 1¼-in. round test bars from it. He then treated this iron so as to introduce oxygen into it, and from this same heat cast additional 1¼-in. round test bars; after treatment the iron contained about 1 per cent of silicon as before. The first set of bars broke very uniformly at from 2000 to 2500 pounds, about the normal for coke iron. The set of bars made after treatment also broke very uniformly, but at from 3800 to 4200 pounds. This iron had the chilling power and closeness of grain of the best grades of charcoal iron. Some 2-in. square test bars were also made from the treated metal and these broke from 19,000 to 24,000 pounds on 12-in. centers. considerably higher than the most rigid specifications for the best grades of charcoal iron. The cost of this treatment is low. It is estimated that the conversion cost will range from $2.00 to $5.00 per ton, according to the daily tonnage converted.

### Heat Treatment of Steel Castings

A paper by Messrs. **C. D. Young**, **O. D. A. Pease** and **C. H. Strand**, of Altoona, Pa., was presented by Mr. Pease.

In an effort to employ cast steel of a stronger structure than that found is the annealed steel castings, the possibilities of heat treatment which will increase the strength without materially decreasing the ductility may be resorted to.

The paper gives a brief outline of what has already been done by the Pennsylvania Railroad Co. at its shops and test laboratories at Altoona, Pa., and is of material interest, as it indicates what may be done with steel castings when properly treated, thereby permitting in railway service greater strength of cast steel parts without any increase in weight or space.

The obscurity formerly surrounding the heat treatment of steel has been for the most part removed by the development of our knowledge of the critical points of steel, pyrometers, furnace construction, and the testing of the finished product.

The operations of the heat treatment proper are taken up under the heads of (1) heating for quenching; (2) quenching; (3) drawing.

(1) *Heating for Quenching.*—Heating for quenching is best conducted slowly, especially in the case of castings of variable thickness. Cracks may occur either in heating or in cooling, due to different temperatures at different points of the casting. The castings should be thoroughly soaked at the maximum temperature (generally 1500 deg. to 1600 deg. F.), 1 hr. being sufficient for sections 1 ft. in thickness. The minimum temperature which will produce the desired hardening effect will, in all cases, be found to be the most satisfactory, as the grain coarsens when the critical range is exceeded to too great an extent. All temperatures should be governed by a checked pyrometer with the hot junction to the heated object, and with several couples in a large furnace to insure a uniform temperature.

(2) *The Quenching Operation.*—The casting should be transferred as quickly as possible from the furnace to the quenching bath, and in the case of large castings, such as locomotive frames, this is by no means a simple matter. The largest castings are best handled by means of cranes and rollers.

The quenching agent employed is generally water or oil, preferably the former, because of its cheapness and drastic cooling effect, more readily breaking up the coarse cast-steel grain. With intricate castings it is generally best to use oil. With water, it is possible to have a large tank and a large running stream, serving to maintain a uniform temperature. Castings should never be thrown in to rest on the bottom of the tank, but should be agitated to prevent the formation of a coating of vapor, retarding the quenching effect. It is also best, whenever possible, to quench the thicker portions first.

(3) *The Drawing Operation.*—Whenever possible, the drawing should be done in a bath of some kind such as lead, barium chloride, a barium chloride-salt mixture, or oil. In the case of large castings this is manifestly impossible, and great care should be exercised in obtaining a uniform temperature in the drawing furnace.

The use to which the casting is to be put determines the drawing temperature, railroad work, by reason of the shock and vibration of the road, requiring high ductility at the sacrifice of some strength.

A table is given showing the results of some tensile, chemical and micrographic tests of commercially annealed and experimentally heat-treated cast steel bolsters. The paper also contains some microphotographs showing the inefficiency of the manufacturer's annealing and the effectiveness of heat treatment. From a diagram giving the average results of a considerable number of tensile tests made from large castings it appears that the heat treatment increases the elastic limit about 50 per cent and the ultimate strength about 25 per cent, without any material change in elongation. The paper was discussed at some length by Messrs. Kone and John Howe.

In the afternoon session the following two papers were read by title, in the absence of the authors:

The American Steel Rail Situation, by R. W. Hunt: Manganese Steel Rails, by Sir Robert Hadfield. The latter paper was discussed by Messrs. W. S. Potter and J. W. Richards.

The paper on blast furnace operation with a turbo blower, by S. G. Valentine, was discussed by Messrs. J. W. Richards, L. Waldo, J. E. Johnson, Jr., and K. Nibecker, the latter two speakers questioning the accuracy of the instrument calibration on which the claimed results are based.

The three papers just mentioned may be found in full in the February issue of the *Bulletin* of the Institute.

Then followed three elaborate papers, of which a report must be reserved for the next issue on account of lack of space in the present number:

Gas Cleaning at the Duquesne Blast Furnace, by A. N. Diehl (the discussion bringing out much interesting information on recent developments at the Edgar Thomson Works).

Utilization of Blast-Furnace and Coke-Oven Gases for Power Purposes, by Heinrich J. Freyn (discussed by J. E. Johnson, Jr., R. Moldenke and R. Lyon).

Pig Steel from Ore in the Electric Furnace, by Robert M. Keeney (discussed by Dr. Richards).

The last paper of this session was presented by Mr. C. B. Murray, on the need of uniform methods of sampling Lake Superior iron ore, which was discussed by Messrs. Kelly and Sweetser.

### Wednesday's Sessions on Mining Law

During the morning session Dr. J. A. Holmes presided.

The paper on The Disposition of Natural Resources, by G. O. Smith, was presented by the author and discussed by Dr. Raymond.

A paper by C. H. Shamel, "Should the Apex Law be Now Repealed?" was read in abstract in absence of the author, and was strongly criticized by Dr. Raymond, who objected with especial vigor to the proposal to have questions of fact decided by the U. S. Geological Survey and not subject to review by the courts. The arguments of U. S. Senator Walsh, of Montana, were in a similar direction.

This discussion was continued in connection with the paper by C. W. Goodale on "The Apex Law in the Drumlummon Controversy."

The morning session was concluded by the presentation of four papers by G. O. Smith, F. F. Sharpless, A. Burch and F. L. Sizer.

During the afternoon session the paper by Horace V. Winchell, who presided in the afternoon, was first presented on Why the Mining Laws Should be Revised. E. B. Kirby's paper on Mining Law Revision—How to Obtain It, followed. Senator Walsh, of Montana, finally gave a review of the present status of mining legislation at Washington. This elicited a general discussion, and it was again and again emphasized that to make a success of it the new code of mining laws should be drafted by experienced mining men who are also familiar with the law—not by lawyers.

### Thursday's Sessions

During the morning simultaneous sessions were again held in different rooms. In one papers on mining geology were presented, while the other was devoted to a very interesting symposium on petroleum or gas. This was continued in the afternoon, while in another room papers on miscellaneous subjects were taken up. These were of a metallurgical character and will be reported in our next issue.

There was a general consensus of opinion as to the success and enjoyment of this meeting. The next general meeting of the Institute will be held in the autumn of 1914 in Salt Lake City, Utah.

---

**Welfare and safety work** among the employes of the Arkansas Valley plant of the A. S. & R. Co., at Leadville, was one of the features of the company's operations last year. A committee having the matter in charge meets weekly with heads of departments to consider the health and safety of employes, and to adopt measures to prevent illness and accident. This movement has proved satisfactory.

**Transvaal Gold Production.**—The number of companies reporting to the Transvaal Chamber of Mines in October, 1913, was 60. The total quantity of ore milled during that period was 2,127,085 tons. There were 9729 stamps in operation with an average duty of 8.62 tons per 24 hours. Tube mills in commission numbered 286. The yield for the month was 718,431 fine ounces gold.

## Recent Chemical and Metallurgical Patents

### Cement

**Testing Portland Cement.**—A convenient test of Portland cement which will effectually show the character of the cement as to permanency or durability when made into concrete is of great importance. Mr. Howard J. Force, chemist and engineer of tests of the Scranton laboratory of the Lackawanna Railroad, has devised an easy and reliable test, as follows: Briquets are made up of neat cement with a sufficient quantity of water to make a fairly plastic mass. These briquets are made in the usual brass molds having a cross-section of 1 sq. in., and are placed in a moist closet, where they are kept for 24 hours. At the expiration of this time a number of these briquets, usually three, are broken in a testing machine, and another like number of the same briquets are boiled under pressure for about 2 hours. The pressure is preferably about 20 atmospheres, or 285 lb. per square inch, which pressure is conveniently produced by placing the briquets in an autoclave or digester which contains water of about 70 deg. F., then closing the autoclave and then raising the temperature of the water by means of a gas flame or other suitable source of heat. It takes usually about an hour to reach a pressure of 285 lb., and this pressure is maintained for about an hour. Upon the expiration of this time the flame is extinguished and the pressure is blown off, which usually takes 20 minutes. The briquets are taken from the water, and if they have not been injured by the boiling they are placed in a moist closet for about half an hour. The briquets are weighed and the gain or loss in weight is noted and the briquets are broken in a testing machine.

It has been found that only cement which is sound in every way and suitable for producing a sound and lasting concrete will resist boiling under pressure successfully. Cements which will pass this test successfully are such as have been carefully manufactured by grinding the ingredients very finely, for instance, so that 85 per cent of the ground material will pass through a sieve of 200 mesh to the inch, then calcined or burned at a high temperature, for instance, 2700 deg. F., and then again ground to about the same fineness, or cements which are made of ingredients which have been thoroughly seasoned for several months after calcination. Inferior cements which are liable to produce unreliable concrete will crack or disintegrate when boiled under pressure or show a decided loss in tensile strength. Practice has shown that a pressure of 285 lb. to the square inch is very effective for producing the conditions which will bring to light the character or quality of the cement under treatment, but this pressure may be varied as circumstances may require. The pressure should, however, exceed 50 lb. to the square inch in order to produce the desired result within a reasonable period of time, and the higher the pressure is kept the quicker the desired result is reached.

One of the advantages of this process is that the briquets will be in condition for testing after a treatment of a few hours' duration. A satisfactory quality of cement will show a considerable increase of tensile strength after having been boiled under pressure, as compared with the same cement which has not been so treated, the increase being 25 per cent or more, and an unsatisfactory quality of cement will crumble or disintegrate under the treatment described. The tensile strength of the cement treated under pressure should not be less than 400 lb. per square inch. The gain in weight by cement during the boiling under pressure should not exceed 1 per cent. The same test is also desirable for ascertaining the character of the cement with reference to expansion. For that purpose expansion bars are made of the cement mixed with water in the usual way with a cross-section of about 1 sq. in. and a length of about 6 in. The bars are placed in a moist closet and at the expiration of 24 hours are carefully measured. They are then placed in the autoclave and boiled under pressure as described, and at the end of that treatment are again measured. Cements which are constant in volume should not show expansion of over one-half of 1 per cent when tested under the above-described conditions. The pressures mentioned herein are measured from the atmospheric pressure as the zero. (1,085,977, February 3, 1914.)

### Gold and Silver

**Slime Filter.**—A new modification of the drum type of filter for the continuous treatment of metallurgical slime has been patented by Mr. **Henry Alinder,** of Milwaukee, Wis., assignor to the Allis-Chalmers Mfg. Co. Fig 1 gives a central sectional view of the machine, while Fig. 2 shows an end view, partly in section, taken on the line III-III of Fig. 1. In brief, the filter consists of a revolving frame onto which are attached a number of wedge-shaped filter cells, arranged between the spokes of the drum. As the drum revolves in a tank of slime, the submerged cells are under vacuum which withdraws the solution and forms a slime cake on the filter surface. As the cell emerges it is put under reverse pressure, which dislodges the cake and throws it into another tank for a second treatment.

Referring to the figures, there are two drums, each in a separate tank 22 and 23, and revolving on hubs 30 and 31, fixed to the shaft 8. The filter cells 2 are constructed of porous material covered with canvas in the usual manner. Each has a pocket 5 connected by pipes 7 and 21, with sources of vacuum and pressure, so that the former can be applied to the submerged cells and the latter to those emerged. Each cell has a discharge opening 3, through which the dislodged cake is directed into the adjacent tank. Spray pipes 1 and 101 are placed conveniently to supply water for flushing the cake from the filter surface. (1,084,383, Jan. 13, 1914.)

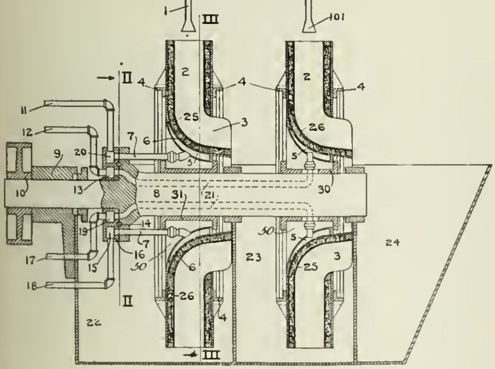

FIG. 1.—SLIME FILTER

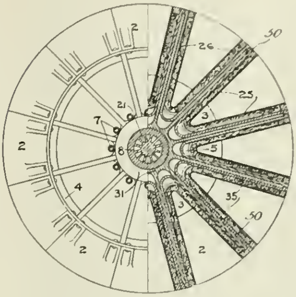

FIG. 2—SLIME FILTER

**Slime Agitator.**—In Fig. 3 is shown a vertical view of a form of mechanical agitator patented by Mr. **Frank E. Marcy,** of Salt Lake City, Utah, and assigned to the Allis-Chalmers Mfg. Co. It consists of a conical bottom tank with a central vertical tube, as in the ordinary form of Pachuca agitator. Instead of using air as the agitating medium, however, the inventor arranges pumping means in a T attached to the lower end of the central tube. Slime can enter the T pipe from either end, where it encounters screw pumps which force the pulp upward through the lift pipe. The screw pumps are placed at 10 and 11 in the figure, and are actuated by a motor 16, pulleys 17 and 18, and shaft 6. If solids should tend to clog in the conical portion of the tank they can be dislodged by introducing air or liquid under pressure through the pipe 15 at the bottom. (1,082,431, Dec. 23, 1913.)

### Copper and Zinc

**Basic-Lined Copper Refining Furnace.**—Improvements in the construction of reverberatory furnaces for copper refining are patented by Messrs. **Lawrence Addicks,** of Perth Amboy, and **Clarence L. Brower,** of Chrome, N. J. It has been customary heretofore to refine copper in a furnace having silicious walls and hearth with a cooling vault beneath. The silicious lining has furnished the necessary acid ingredient to slag off impurities in the copper, but the slag formed has been excessive, and there has been danger to the furnace structure from the consumption of the silica lining. The present inventors make use of magnesia

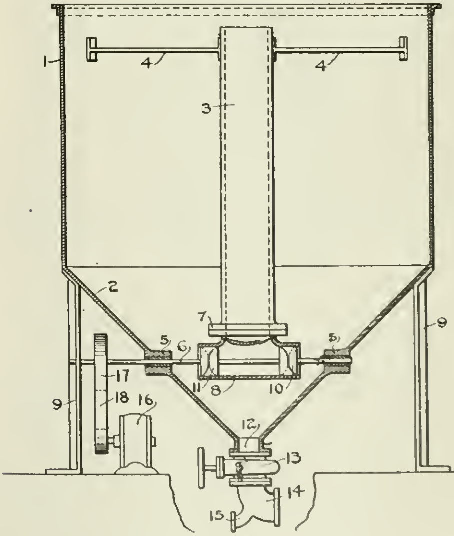

FIG. 3.—SLIME AGITATOR

brick in the hearth and chrome brick in the roof and walls, and find these materials superior to silica for the purpose. The furnace is constructed of a concrete and brick base, on which clay brick are laid in the form of an inverted arch. On this is laid the magnesite brick hearth, also in the form of an inverted arch, between skew-backs which receive the thrust and communicate it to the side supports. By a special construction the brick of the hearth are continued to the skew-back, beneath the side walls, and form a suitable base on which to build the walls. The magnesite bricks are laid in a mortar of magnesite dust and silicate of sodium solution.

Three classes of material ordinarily are dealt with in such furnaces: (1) Foul, such as junk, cement copper, etc.; (2) normal, such as blister copper from converters; and (3) pure, such as cathode copper. The basic-lined furnace is superior to the acid-lined furnace for the treatment of these materials. In the case of foul material the basic furnace permits separate treatment, with production of less slag and less danger to the furnace structure. In the case of ordinary blister copper the quantity of slag formed in the basic furnace is less than in one lined with silica. This is true also with cathode copper, where the slag formed amounts to less than one-half per cent with the basic furnace as compared with 3 per cent in the silica-lined furnace. Also, with the basic furnace this pure material requires only melting, whereas in the acid-lined furnace the same cycle of operations is gone through as in treating blister copper. (1,083,719, Jan. 6, 1914.)

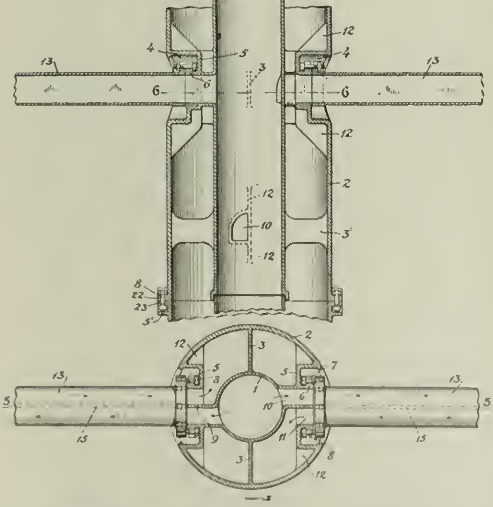

FIG. 4.—COOLING RABBLE ARMS IN ROASTING FURNACES

**Improved Form of Zinc Retort.**—The ordinary clay retorts used in spelter production are tubular in form and have appreciably flat surfaces on which slag dripping from a broken retort in an upper tier may lodge and ultimately puncture the wall and thus destroy an otherwise good retort in a lower tier. In order to obviate this destruction of retorts, Mr. **Harold W. Webster**, of Billericay, England, has patented a form having a sharp ridge along the top outside, resulting in increased thickness at this point and offering no surface on which dripping slag can lodge. The retort has a thickened and exteriorly flattened bottom which provides increased durability and a secure base for the support of the retort in the furnace. The rounded interior shape is preserved at both top and bottom of the retort.

### Fumes

**Mechanical Purification of Smelter Fumes.**—The recovery of mechanical impurities and the purification of the gases in smelter fumes is the subject of a patent granted to Charles S. Vadner, of Salt Lake City, Utah. The patent, in fact, refers to an acid smelter fume filter. The inventor in Fig. 5 shows its application to smelter fumes in general. The fumes coming from the smelter flue are led through the intake flue 1 into the recovery tower A, which has a sloping bottom 1', sloping away from the intake flue, while above the entrance of the intake flue there is a grate made of chemical bricks, 3, with suitable apertures entirely across the base of the recovery tower. Resting upon these grates are a number of spherical bodies, 4, of suitable size and character. The opening of the grate, 3, is smaller than the diameter of the bodies, 4. In the center of the recovery tower is a rotary stirrer, 5, with stirring arms, 6, provided with a pulley, 7, or other suitable means for the operation of the same outside of the recovery tower. These spherical bodies completely fill the recovery tower, and are prevented from falling into the outlet, 9, by the grate, 3, which is composed of chemical bricks, insoluble in acids, set at suitable intervals across the opening in the outlet. The fumes percolating upward through the irregular apertures between the suitable spherical bodies lose all their mechanical impurities, which become disposed in the interstices between the spherical bodies. The rotary stir, 5, is rotated, and by agitating the spherical bodies the mechanical impurities, consisting of gold, silver and other valuable metals, are permitted to fall down through the spaces in the brick grate to the sloping floor, 1, thence they may be drawn off through a manhole and returned to the smelter for the recovery of their valuable constituents. In this way all mechanical impurities are intended to be filtered from the fumes, preparatory to their passage onward through the outlet into other gas-treatment apparatus, where any combustible gases contained therein and other values are to be recovered. (1085712, February 3, 1914.)

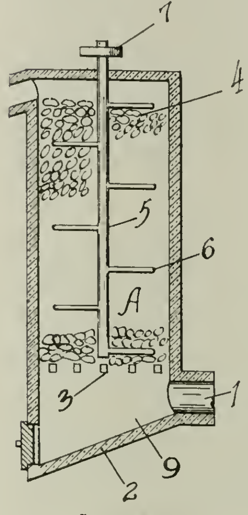

FIG. 5.—FUME FILTER

### Metallurgical Furnaces

**Cooling Rabble Arms.**—In roasting furnaces of the superimposed-hearth type it is advisable to cool the rabble arms in order to increase the life and efficiency of the furnace. Mr. **John B. F. Herreshoff**, of New York City, has recently patented an improved form of construction in which the central rotating member and the rabble arms are efficiently cooled by currents of air. As shown in Fig. 4 the central rotatable shaft to which the rabble arms are attached, consists of a central portion 1 and a concentric sleeve 2, held in concentric relation by strengthening ribs 3. At points of attachment of the rabble arms the walls of the sleeve 2 are recessed to form pockets 4. From the innermost walls of these pockets extend semi-circular flanges to which the rabble arms are attached by bolts. Each flange is provided with a vertical partition 9 which, together with the walls of the flange on one side of the partition, extends to the inner shaft 1 to form a passage 10. Each rabble arm is provided with a semicircular flange and with a central vertical partition from its inner end to a point near its outer end. Thus when the rabble arms are in place there is provided a continuous path for cool air from the inner portion of the shaft through one side of the rabble arm, back through the other side and into the inner portion of the shaft. The air current may be induced or forced in the usual manner. (1,085,419, Jan. 27, 1914.)

**Convertible Crucible-Retort.**—By the use of a particular type of crucible and cover in an ordinary tilting furnace, Mr. Willis W. Case, Jr., of Denver, Col., has made an invention which permits the use of the furnace for melting or retorting as desired. (1,085,540, Jan. 27, 1914.)

### Production of Thorium

**A method of producing metallic thorium** in a condition suitable for the manufacture of filaments for incandescent lamps has been patented by **Mr. William C. Arsem** and assigned to the General Electric Co. Metallic thorium hitherto produced has not been suitable for use as a filament, but according to the inventor's process it may be so produced. He converts thorium dioxide into thorium tetrachloride, and reduces this salt with sodium in a vacuum. The metal thus produced is washed and then compressed into a dense metallic state, from which hammered or drawn metal may be produced. (1,085,098, Jan. 27, 1914.)

## Synopsis of Chemical and Metallurgical Literature

### Iron and Steel

**Sintering Iron-Bearing Materials.**—The agglomeration or sintering of finely divided iron-bearing materials has become an important adjunct to the iron and steel industry, by rendering available for reduction in the blast furnace certain materials hitherto useless for that purpose. Thus, blast-furnace flue dust, finely divided concentrates and similar substances have been converted into a suitable blast-furnace feed. In the "Proceedings" of the Engineers' Society of Western Pennsylvania for December, 1913, Mr. B. G. Klugh presented the latest developments in this industry as exemplified in the Dwight & Lloyd process. This method of sintering was originally developed as a roasting process for sulphide ores in non-ferrous metallurgy, and is now widely used in that industry. Its extension to the iron field was a subsequent development, but is now recognized as an important means of agglomerating iron-bearing materials when mixed with a suitable proportion of fuel. There are now five Dwight & Lloyd plants in operation on iron materials, and thirty-eight in non-ferrous metallurgy. The iron plants treat pyrite cinder, flue dust, high-sulphur magnetites, magnetic concentrates, fine hematites, limonites and roll scale. For all except the flue dust it is necessary to add the requisite fuel.

The potent factor in operating this process is to maintain a permeable bed of mixture on the sintering hearth. This is affected by the quantity of water added, the method of adding the water and the method of delivering the mixture onto the hearth. The bed must be uniform in depth and consistency and the volume of gases passing through every square inch of bed should be progressively the same. Ignition is another important factor in efficient operation. Each mixture has an intensity of ignition for its most efficient sintering operation. Different fuels may be used. Of the five plants mentioned above two use fuel oil, two natural gas and one artificial gas. Fuel oil consumption is ¼ to ½ gallon per ton of product; natural gas, 60 cu. ft. per ton. Gasoline has been used and abandoned, but coal may be used advantageously under local conditions.

Early experience with the Dwight & Lloyd machines indicated a high loss of grate bars when sintering flue dust with a high fuel content, say 25 per cent. Since only about 8 per cent is necessary for sintering, the balance was burned out at the expense of the grates. Later this difficulty was overcome by covering the grates with a layer of lime or with coarse sinter which had been screened from the cake as it discharged from the machine.

While high-carbon flue dust can be sintered, it is considered advisable to use low-carbon material when possible. This can be secured either by concentrating the high-carbon dust or by diluting it with other fine material containing no fuel. The latter has been deemed the more profitable practice, although it is admitted that concentration yields a better material for sintering.

As examples of the value of sinter as a furnace feed, the author cites an Eastern furnace carrying a burden of 25 per cent sinter from flue dust and magnetic ore. With this charge the fuel has been about 10 per cent lower than before, when sinter was substituted for an old-range ore. There has been an absence of slips and scaffolds, and no action of scouring. A Southern furnace formerly carried a burden consisting of ¼ to ⅜ rotary kiln nodules, but never over ⅜ on account of scaffolding and scouring. Sinter has since been substituted and carried to the extent of one-half the burden, with a decrease in coke consumption, more regular driving and increased output.

In desulphurizing, the Dwight & Lloyd process has been successful in reducing sulphur in cinder from 2.0-6.5 per cent down to 0.10 per cent. Magnetite with 1.5 to 4 per cent sulphur has been reduced to 0.15 per cent.

The cost of operating a plant of two units is given in round numbers per ton as: labor, 18 cents; ignition, 6; repairs, 6; power, at 8.8 kw-hr. per ton, 16; total, 46 cents.

With cheap natural gas the cost for ignition would be only a fraction of a cent.

In the discussion it was brought out that material containing sulphur in combination with calcium and barium could be desulphurized to less than 0.1 per cent.

Weathered flue dust sinters better than fresh one. Different fuels can be used in the sinter mixture, as coke breeze, bituminous coal and anthracite screenings. In some experimental work charcoal, sawdust and lignite coal had been used successfully. Fuel containing sulphur does not affect the ultimate result in desulphurizing pyrite cinder. The quantity of air drawn through the bed is in excess of chemical requirements by from 50 to 80 per cent. The best pressure in 13 in. water gage.

It is preferable to use a constant-speed fan and regulate the permeability of the charge to conform to varying air requirements.

### Gold and Silver

**Flotation of Antimonial Silver Ore.**—In the November, 1913, "Quarterly" of the School of Mines, Columbia University, Mr. **Donald G. Campbell** describes a study of flotation as applied to a silicious ore containing pyrite, stibnite, and sulphides and antimonide of silver totaling about 5 or 6 per cent. The mineral was finely disseminated through the gangue, and necessitated fine grinding for its liberation. The ground pulp was subject to treatment according to the minerals' separation process of flotation, being mixed with water, oil and acid, and agitated to form a froth containing the mineral concentrate.

The oils tested were cylinder and machine mineral oils; sperm, fish and whale oils; corn, cottonseed and rapeseed oils; China-wood oil; resin oil; pine and pine-tar oils. In different experiments the effect of varying the acid, rate of agitation and temperature were tested. The summary of results shows:

1. Pine-tar oil was the most effective froth producer, and was most efficient when used in quantities approximating 0.1 per cent of the ore.
2. Without acid the froth is non-selective; that is, gangue is floated equally as well as mineral. The amount of strong sulphuric acid that seemed to produce the best results was approximately 0.4 per cent of the ore.
3. For good extraction the peripheral speed of the agitator blades had to be from 100 to 1200 ft. per minute.
4. Extraction increased with increase in temperature, and less oil and agitation were necessary. The amount of gangue carried into the froth was greatly lessened at higher temperatures.

### Copper and Nickel

**Roasting Copper-Nickel Matte.**—A study of some of the reactions taking place when copper-nickel matte is roasted is published by Messrs. **Edward F. Kern** and **M. H. Merris** in the Columbia School of Mines "Quarterly" for November, 1913. A summary of the results shows that in the analysis of copper-nickel materials copper may be separated from a sulphate solution by boiling with metallic aluminium in the presence of about 3 c.c. concentrated $H_2SO_4$ per 100 c.c. volume. When a mixture of nickel sulphide and copper oxide is heated small amounts of copper and nickel sulphates are formed when the temperature is between 525 deg. and 600 deg. C. Above 650 deg. C. these sulphates do not form, but cuprous sulphide and mixed subsulphide are formed; the higher the temperature the more rapid the formation of the cuprous sulphide. Nickel subsulphide is shown to be a stable compound, and does not react with copper oxide when a mixture is heated.

The roasting of nickel-copper matte proceeds slowly at temperatures below 600 deg. C. Above 730 deg. C. the matte becomes pasty and is not easily oxidized. The best conditions for rapid and complete roasting are, first roast for an hour at 450 deg. to 500 deg. C., with free access of air, in order to coat the matte particles with the thin film of oxide. The temperature can then be raised to between 675 deg. C. to 725 deg. C. Rabbling is necessary to prevent sintering of the mass.

### Tin

**Crushing Tin Ore with Nissen Stamps.**—Comparative tests of the value of Nissen and California stamps in crushing Cornish tin ore were recently made at the South Crofty tin mine, Cornwall. The results are reported in the *South African Mining Journal* for Nov. 8, 1913. Two Nissen stamps were run against 10 California stamps which are in the South Crofty mill. The following data show the comparative performance of the two types of stamp:

| | Two Nissen stamps | 10-stamp S. Crofty |
|---|---|---|
| Weight of stamps (lb.) | 2000 | 1050 |
| Number of drops per minute | 94 | — |
| Height in drop (in.) | 9 | — |
| Mesh of wire screen | 14 | 14 |
| Tons of ore crushed (2000 lb.) | 5.6 | 5.6 |
| Hours run | 6.50 | 3.25 |
| Tons per stamp per 24 hours | 10.33 | 3.75 |
| Units of power per hour | 7.85 | 20 |
| Cost of power per ton crushed (pence) | 5.46 | 6.96 |

*Grading Analysis.*

| | Nissen Stamps | | South Crofty Stamps | |
|---|---|---|---|---|
| | Dry Per cent. | Wet Per cent. | Dry Per cent. | Wet Per cent. |
| + 20 mesh | 3.6 | 3.5 | 2.7 | 2.2 |
| + 40 mesh | 22.4 | 22.7 | 17.4 | 16.9 |
| + 60 mesh | 9.9 | 10.9 | 8.5 | 8.0 |
| + 100 mesh | 20.8 | 18.8 | 20.5 | 19.2 |
| + 150 mesh | 10.6 | 7.0 | 8.0 | 7.1 |
| — 150 mesh | 32.7 | 37.1 | 42.9 | 46.6 |

The wet screen grading analysis, done to determine the amount of minus 200-mesh product produced, gave the following results:

| Discharge | Nissen stamps | Sth. Crofty mill |
|---|---|---|
| + 200 | 67% | 61% |
| — 200 | 33% | 39% |

The Nissen stamps have also been run on Carn Brea ore, and the results of the different trials are given below:

| Test No. | 1 | 2 | 3 | 4 |
|---|---|---|---|---|
| Weight of stamps (lb.) | 2,000 | 2,000 | 2,000 | 2,000 |
| No. of drops per minute | 92 | 94 | 94 | 94 |
| Height of drop (in.) | 7 | 9 | 9 | 9 |
| Class of screen used | Wire | Wire | Wire | Cornish |
| Mesh of screen | 10 | 10 | 20 | 36 |
| Aperture, in inches | .654 | .064 | .028 | .028* |
| Tons ore crushed (2000 lb) | 12.20 | 17.75 | 3.36 | 5.26 |
| Hours run | 12.38 | 15.76 | 4.39 | 7.46 |
| Tons per stamp per 24 hours | 11.82 | 13.5 | 8.76 | 8.1 |
| Units of power per hour | 7.62 | 7.85 | 7.85 | 7.85 |
| Cost of power per ton crushed (pence) | 4.63 | 4.18 | 6.54 | 6.93 |

*Approximate.

*Grading Analysis*

| Test No. | 1 | 2 | 3 | 4 | |
|---|---|---|---|---|---|
| | | Dry % | Dry % | Dry % | Wet % |
| + 20 mesh | * | 13.1 | — | — | — |
| + 40 mesh | * | 23.1 | 14.0 | 5.4 | 5.1 |
| + 60 mesh | * | 9.8 | 10.9 | 13.3 | 12.9 |
| + 100 mesh | * | 19.9 | 24.2 | 28.1 | 27.3 |
| + 150 mesh | * | 8.9 | 12.5 | 10.5 | 9.4 |
| — 150 mesh | * | 25.0 | 38.4 | 42.7 | 45.3 |

*No samples taken.

The tests with Nissen stamps, we are informed, were all very much interrupted through lack of water, and it is considered that with regular running still better results would be possible. The result of the test in which a Cornish screen was used is regarded as particularly satisfactory, the screen analyses showing a much more granular pulp than usually obtained in Cornwall. This goes to confirm the opinion held by the inventor and manufacturers of the Nissen stamp that this mill would give not only an increased output at a lower cost for power, but also contribute to the securing of a higher tin recovery ratio, inasmuch as it would produce less slimes.

---

**Cement production in the United States in 1913** amounted to about 92,406,000 barrels, according to preliminary estimates of the Geological Survey. This is an increase of about 12 per cent over 1912. The average value per barrel is considered to be appreciably higher than in 1912. Increases of 10 to 25 cents per barrel have been reported from Rocky Mountain plants.

**Bureau of Mines publications** recently issued include **Technical Papers** 50, on metallurgical coke; 54, on errors in gas analysis due to assuming molecular volumes of all gases alike; 58, on the action of acid mine water on the insulation of electrical conductors; and **Bulletin** 58, on fuel briquetting investigations.

## Pressure Air-Cooled Roaster Furnace

The new Herreshoff pressure air-cooled roasting furnace has been brought to the attention of the metallurgical world within the last two years, although the furnace in its present development has been in use in acid works for a long time.

The furnace has been developed as the result of experiments with various sulphide ores for the purpose of making sulphurous acid gas. These experiments were conducted under the able direction of Dr. J. B. F. Herreshoff with the idea of designing a furnace which permits the use of higher temperatures than heretofore thought possible, without localizing a heat of such intensity as to endanger the slagging of the ore body, or destroying the working parts of the furnace.

To attain the above results, a long series of experiments were carried on, using such well-known cooling mediums as water, partially water and partially air, but these were found unsatisfactory in producing the ultimate results desired. The pressure air-cooled system was then adopted as it performed all the necessary functions, and at the same time simplified the construction and operation, to say nothing of permitting the utilization of waste heat.

The pressure air-cooling effect in the furnace is obtained by forcing air at 1 oz. to 3 oz. pressure by means of a fan, into the bottom part of the shaft, which conveys it to the arms, and thence in its heated state to the ouside air, or to the bottom hearth of the furnace for combustion, or both.

The shaft is made double, similar to any jacketed vessel, the outer shaft or tube being made of cast iron, the inner one of cast iron or steel. The rabble or rake arms are also made with this double effect, the inside tube of the arm connects with the inside tube of the shaft, while the outside tube of the arm connects with the outside tube of the shaft. The air supplied by the fan enters the main tube of the shaft, passes through the inner tube of the arm, thence through the outside arm and shaft tubes to the top of the furnace. Here it is either discharged to the open air, at temperature of about 400 deg. Fahr., or carried to the bottom or cooler parts of the furnace for combustion, either through the temperature control flues or the bustle pipe, or both.

The temperature control flues in combination with the bustle pipe and return pipes for waste heat perform two very valuable functions. The temperature control flues absorb the excess heat from the hottest zones of the furnace, and transmit it to the cooler ones; the return pipes take the waste heat from the top of the furnace and discharge it at the bottom or cooler zones of the furnace for combustion purposes.

It is plainly comprehensible, and has proven out by actual practice, that the embodiment of these two features will give a maximum capacity of sulphur per square foot of hearth area, without endangering the slagging of the ore body, due to localization of an intense heat in the central zones of the furnace.

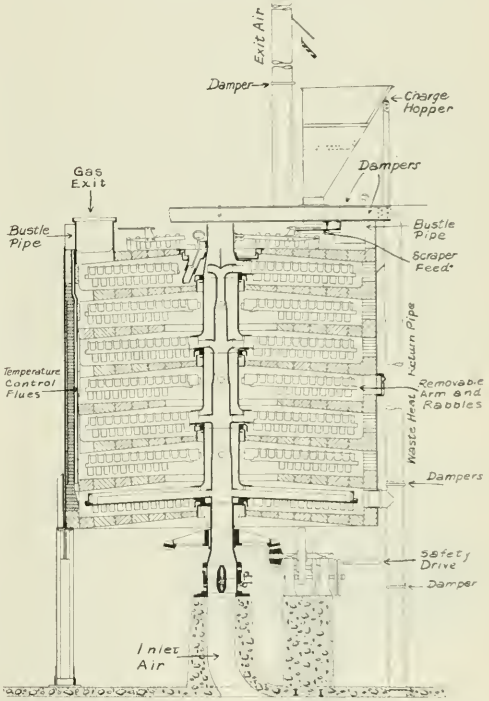
A detail feature which applies in our furnace is that the amount of air necessary to give sufficient cooling to the shaft and arms is approximately the amount necessary for combustion, making the temperature of the waste heat to be returned a maximum, thus giving the greatest efficiency for the utilization of the same. The damper control makes it possible to use just as much of the waste heat as desired, so that the control is flexible, making the furnace adaptable for burning various grades and quantities of ore within reasonable limits.

The removable rabble arms are made of standard steel pipe which makes them light for handling, and easily attainable at small cost, and their durability has proven superior to cast iron under actual working conditions.

The removal of the arms has proven by experiment a very simple and rapid operation, the same being performed on a hot furnace.

The removable rabble teeth are so designed, in regards to their pitch and progression, that they maintain a uniform thickness of ore bed over the entire hearth surface, and by means of the back and forward rabble effect the surface of the ore exposed for combustion is greatly increased.

These two features, the former permitting the ore to remain the greatest length of time in the furnace and the second exposing a larger surface for combustion, mean maximum capacity with thorough desulphurization.



HERRESHOFF AIR-COOLED ROASTER FURNACE. (TYPE SHOWN IS OF MEDIUM SIZE, SPECIALLY ADAPTABLE FOR A DEAD ROAST)

The openings for the passage of the gas between the hearths are designed so as to reduce the velocity of the gas to about 270 ft. to 300 ft. per minute, about one-third of the velocity found in most furnace designs, thus preventing the formation and entrainment of dust.

The ore feed is a very important feature. This is composed of a telescopic device attached to the hopper, which feeds the ore in a cone-shaped pile to a plate. From here it is scraped by knife edges, attached to the revolving drying hearth rabble arms, and when once set this simple indestructible feed delivers a constant quantity of ore to the hearth without further regulation. The ore then passes across the top of the drying hearth, in a thick or thin bed, as desired, according to the moisture in the same, and the variation of the speed of travel can be regulated by adjusting the relative position of the rabble teeth.

From the drying hearth the ore passes onto the furnace proper through a telescopic feed which also acts as a gas seal. This feed and dryer has proven very efficient in furnishing the furnace with a constant quantity of thoroughly dried ore which is essential for good operation.

A few words in regard to some of the details of construction may prove of interest. The shaft, flues, etc., are designed so that they are easily removable and wherever wrought iron or steel is used, it is either air-cooled or properly protected.

The bearings top and bottom insure perfect shaft alignment, and are so constructed that the horse-power for operation is reduced to a minimum.

The patent safety drive insures the rabble arms, teeth and shaft from breakage, should any foreign matter block the arms.

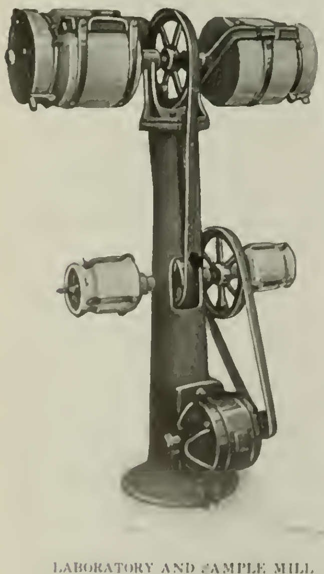
The furnaces are equipped with a sufficient number of specially designed doors, which are built for stability and convenience of operation. They are nicely machined and provided with sight holes, which are self-locking, making a gas-tight apparatus, not like the ordinary door which is not tight at the beginning, sulpates in a short time, and lets so much gas escape that the burner room, which should be a pleasant place to work, becomes a very disagreeable one.

In this article we have confined ourselves to points which apply on all furnaces, whether they are for a dead or metallurgical roast, and these principles also apply where extraneous fuel has to be used.

This furnace was developed by the General Chemical Co. through its Herreshoff Furnace Department.

## Laboratory and Sample Mill

The Abbe Engineering Company, of New York City, has added another mill to their large line of machines by putting on the market their combination laboratory and sample mill. This is really a combination of various sizes of their laboratory mills, fitted to a stand which makes a machine that is easily accessible from all sides, and being self-contained, may be placed in any part of a laboratory.



LABORATORY AND SAMPLE MILL

Where different diameter jars are used different speeds are obtained by means of belts and pulleys or silent chain gearing. A large number of different sized jars can be mounted on this type of machine, according to the requirements.

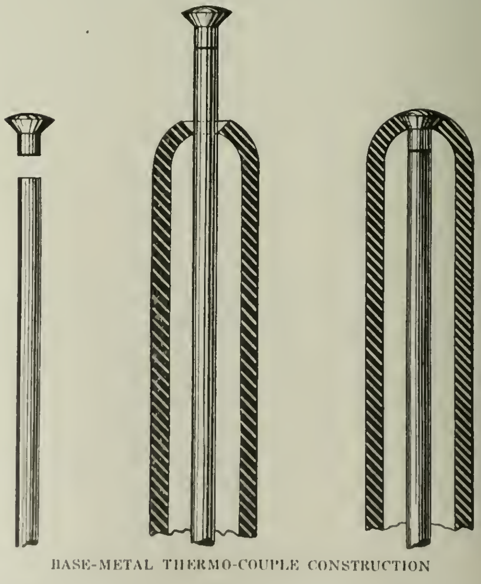
A novel feature is the motor fastened to the shaft of the column. This motor may be run from any commercial electric supply circuit and can be fed from any electric light socket. Another feature is that the mill being on its own arm pedestal a separate stand or table is not required. This also avoids the discomfort of stooping to change jars, when the mill is on the floor. When it is not desired to run the machine with a motor a pulley is furnished which may be belted to a line shaft.

## New Base-Metal Thermo-Couple

A new type of base-metal thermo-couple has just been put on the market which has several decidedly novel features of construction. The most frequent source of complaint of the ordinary base-metal couple emanates from its lethargy in indicating fluctuations. This has been due to the protection given the couple itself. Ordinarily this protection consists of an iron or steel tube through which the heat must travel and then heat the air within before it reaches the active portion of the couple, which in turn acts upon the instrument indicating the temperature.

In some cases this lag has amounted to 30 minutes, meaning that the actual temperature could not be read until 30 minutes had passed after exposing the couple to the heat of the frnace. This is about as bad a case as depending upon a watch which gets you to the depot 30 minutes after the train has left.

This great objection has been overcome in one type of couple by enclosing one of the elements in the second one, which is of tubular shape. The elements are welded together at the end and the couple is used in this form mostly without additional protection, making it thereby an exposed couple. But the products of combustion are liable to attack the couples and rapidly oxidize the exposed portions, and especially when immersed in molten metals the interior wire or rod, which is supposed to be the protected element of the couple, is gradually eaten into from the small portion of its exposed end.



BASE-METAL THERMO-COUPLE CONSTRUCTION

The new "simplex couple" brought out by the Stupakoff Laboratories of Pittsburgh combines the good qualities of the two types just described, and at the same time eliminates objectionable features. While the solution is exceedingly simple, it is unquestionably effective. It is accomplished by introducing as a new feature an internal weld, which forms the point of junction between the two elements of the thermocouple. One of the elements is a rod or a wire, and the second one, inclosing it, is of tubular form. A button consisting of the identical material as that of which the outer element is made is welded to the inner element, and after introducing this into the outer tube the head of the button is welded to the open end of the latter. Thus, the junction itself remaining at the very end, the completed entity represents a typical form of the exposed couple.

The accompanying illustrations, which are copies of drawings accompanying the application for United States patent, now pending, plainly show the various steps followed in the manufacture of this new device and need no additional explanation.

## A New Chemists' Slide Rule

By Harry R. Lee

The Keuffel & Esser Company, 127 Fulton street, New York City, have recently placed upon the market a new type of slide rule especially designed to meet the needs of chemists engaged in commercial analysis. The designer of this excellent rule and the author of the manual which is issued in connection with it, is Dr. R. Harmon Ashley, of the Chemical Department of the University of Maine. As the name implies, it may be used in the solution of any problem in stoichiometry within the list of elements and compounds printed on the rule.

Referring to the usual engineers' slide rule for nomenclature, the regular or front side of the chemists' rule shows the molecular symbols of 46 salts and 10 acids and bases on the A scale of the frame and a parallel list of these on the B scale of the slide. On the back appear the symbols of 42 elements and 37 oxides in place of the usual A scale on the frame, and a parallel list of these on the B 1 scale of the slide. The C and D scales on the front and the C 1 and D scales on the back are graduated numerically as is usual on the engineers' slide rule.

The principle of the application of the rule to the handling of chemical symbols and the corresponding atomic and molecular weights is clearly understood after passing the runner to a few of the elements on the A scale and reading under the runner on the D scale; in each case it will be seen that the atomic or molecular symbol with its graduation exactly corresponds in position with the proper atomic or molecular weight as numerically expressed on the D scale. The elements and compounds are, therefore, arranged in a list according to the ascending numerical values of their atomic and molecular weights and in no way does this arrangement depend upon alphabetical or chemical grouping. The symbols sought are located by approximate knowledge of their weights.

FIG. 1—FRONT OF CHEMISTS' SLIDE RULE

As in every application of the slide-rule principle, the distance of each symbol graduation from the left-hand index-line of the rule is proportional to the logarithm of the numerical value of the weight corresponding to the symbol. Salts and oxides are provided with short graduation lines, while acids, bases and elements have longer lines; this, with a little familiarity with the instrument, enables the operator to identify the line of the symbol for which he is looking, especially where approximately equal atomic or molecular weights of different substances necessarily crowd the graduation and printing.

The symbols listed comprise about all which will be needed by the chemist in ordinary commercial practice and is a remarkably good selection for the purpose. Those who need many symbols not given on the rule will for the most part be chemists working in the rarer elements and compounds, the nature of whose work will call for closer methods of calculation than a slide rule could possible afford.

In those cases where a molecular weight has not been inscribed on the rule, it is often possible to read off the weights of two, rarely more, compounds, the sum of which will give the molecular weight desired. Setting this sum on the proper numeral, the rest of the calculation will proceed as usual.

The sacrifice of the A and B scales on the front and of the A and B 1 scales on the back side of this rule to make space for the chemical symbols is the only way to effect the purpose of the designer. Those who will miss these features will recollect, however, that stoichiometrical calculations do not involve squares and cubes, or the corresponding roots and will turn to an engineers' rule for this class of calculation.

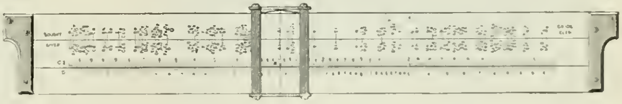


FIG. 2—BACK OF CHEMISTS' SLIDE RULE

The rule will assist in the solution of any stoichiometrical calculation, but is more particularly adapted to save time in handling the simpler ones, where most of the terms of the written expression are found to be molecular or atomic weights. In the extreme case of gas volume evolved from a reacting solid substance, the expression will involve the molecular weight of the latter, the gas factor 22.4, two temperature factors and two pressure factors, the result being the volume of gas at a prescribed temperature and pressure from a given weight of reacting solid. In this case 5 of the 6 factors being numerical and known, an ordinary slide rule would do nearly as well, with reference to convenience or time consumed, the rule furnishing only one chemical weight.

A feature of the rule which will appeal to some, who do not make a point of remembering the atomic and moleculer weights of a large list of elements and compounds, will be found in the fact that the numerical value of any of the 135 symbols listed may be read off on the scales D by the use of the runner, accurate to the first decimal place at least, depending on the region of the scale where the value may be found. For ordinary purposes the exact knowledge of the second decimal figure is unessential, and this will change yearly for many elements as new determinations are published. No changes of sufficient magnitude will occur, however, to place the rule out of date and it is built to last a lifetime of good care.

The manual is a pamphlet of 25 pages, written in a singularly clear and simple style, intelligible to those who have no acquaintance with the properties of logarithms and brief and clear enough to meet the needs of the technical man who wishes to know in the least time what he can do with the rule. The manual ends with a neat dissertation on the maximum error necessary in reading on three regions of the scale, which is unusual and gratifying to note. It is emphasized that the results from the rule are of as high order of accuracy as the chemical work which precedes its use, usually is expected to be. The reciprocal method of calculating any percentage is unique and very neat.

Holcomb Rock, Va.

## A Self-Cleaning Screen for Sewage and Trade Wastes

In order to dispose of sewage and trade wastes in a sanitary manner, unusual efforts have been exerted to meet these requirements by a successful separation of the solids contained in the sewage and the clarification of the effluent to such a condition that it can be discharged to streams without polluting them.

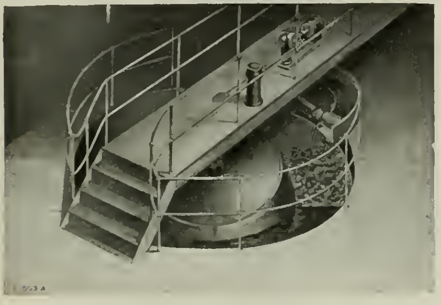

FIG. 1—RIENSCH-WURL SCREEN IN SERVICE

To accomplish this, various tank treatments have been devised. Septic tanks, plain sedimentation, and more recently Imhoff or Emscher tanks have all had more or less vogue with engineers and have all proven to have more or less objectionable features, or to develop such objectionable features under conditions of service. In consequence of this the demand has been growing for an immediate system of treatment that would provide for the recovery as a by-product of the values contained in sewage, and be also suitable for like purposes in the industrial field.

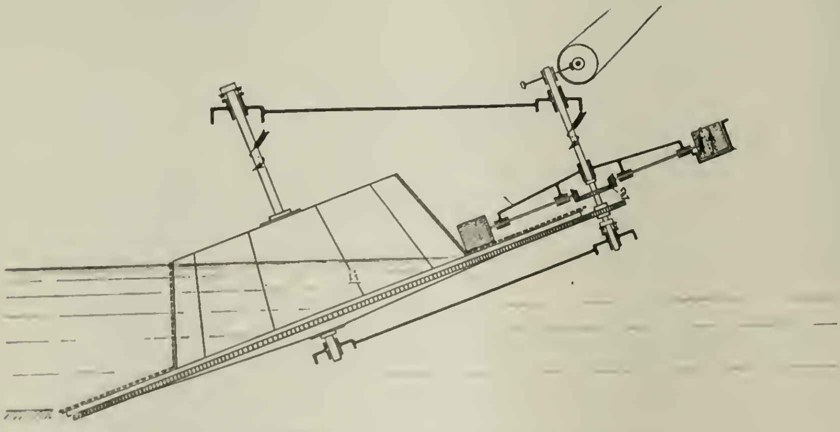

FIG. 3—ELEMENTARY OUTLINE OF RIENSCH-WURL SCREEN

The Riensch-Wurl rotating self-cleaning disc screen has proven a mechanical device capable of successfully accomplishing the desired results. This screen has been developed in Germany as a result of persistent experimenting to produce a fine screen that would automatically clean itself as well as collect a very large amount of the floating and suspended matter in the sewage and deliver the screenings in a sufficiently dry condition to be readily handled with a spade or conveyor system.

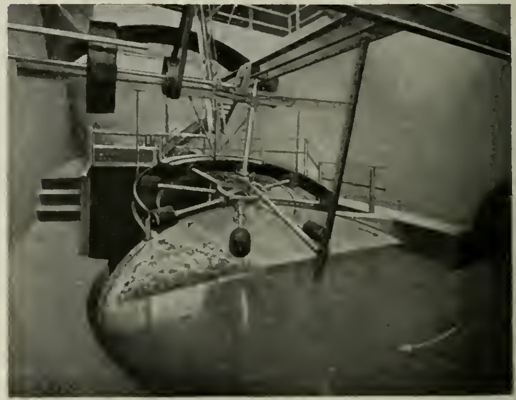

FIG. 2—RIENSCH-WURL SCREEN IN SERVICE

The screen consists of a perforated disc, set at an angle of 10 deg. to 25 deg. to the flow of the sewage, and revolving slowly on a shaft normal to the disc. The solids carried to the screen collect on it and are carried above the surface of the sewage by the rotation of the disc and there allowed to drain, after which the face of the disc is swept by a set of revolving brushes carried on a "star" driven by a shaft parallel to the shaft of the disc. As each portion of the screen surface is swept five or six times by the brushes the result is a thorough cleaning of the screen plate. These screens are made usually with apertures of 2 mm. (5/64 in., or 79 mils) wide by 30 mm. (1 3/16 in.) long, but are sometimes furnished with apertures or slits 1½, 1, or even ¾ mm. (59, 39, 29½ mils) wide.

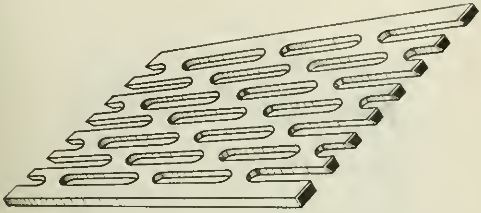

FIG. 4—SECTION OF RIENSCH-WURL SCREEN

The general appearance of this screen is shown in Fig. 1, while Fig. 2 shows a screen in which the central conical screening surface is omitted, but the method in which the screen operates is clearly shown.

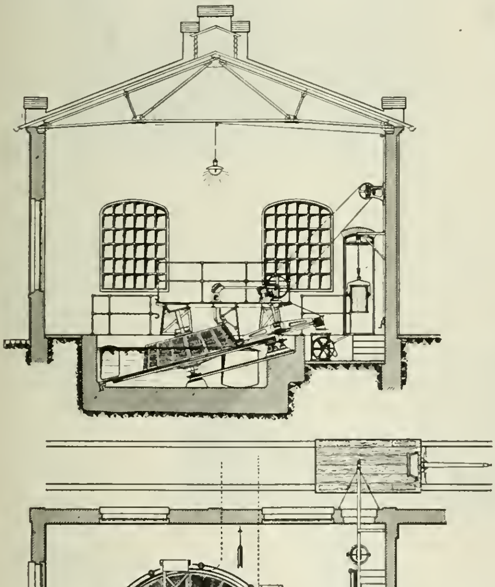

FIG. 5—TYPICAL INSTALLATION OF RIENSCH-WURL SCREEN

The arrangement of the machine will be better understood from the drawing, Fig. 3, while the screen plate is shown in Fig. 4, the tapered openings of which are varied to suit the particular requirements of service to be rendered.

Figs. 5 and 6 are typical installations of the screen alone and with pumping plant, while Figs. 7 and 8 show interior view and layout of the sewage treatment plant at Dresden, Germany, containing four screens, 8 meters in diameter.

The Riensch-Wurl screen is now being introduced in this country by the D'Olier Centrifugal Pump & Machine Company, of Philadelphia, after an extended stay of Mr. William L. D'Olier in Europe, where he studied and invesigated foreign sewage-disposal apparatus and processes.

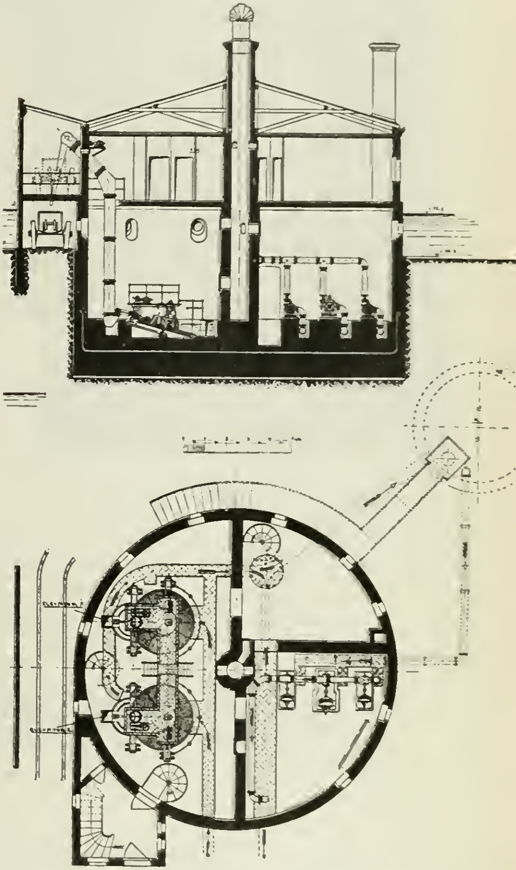

FIG. 6—TYPICAL INSTALLATION OF RIENSCH-WURL SCREEN AND PUMPING PLANT

The Riensch-Wurl screen is not only successfully and satisfactorily clarifying sewage and producing an effluent which is permitted to be discharged directly into the public waters of European countries, but is also removing the solids in the form of so-called sludge with such a minimum content of water as to render this easily handled and transported and in such a condition as to insure a maximum recovery of by-product in grease and degreased sludge, insuring actual financial returns from the operation.

In the process of handling sludge from various tanks, drums and from the Riensch-Wurl screens, a further reduction in water content is necessary, and a continual effort has been made to produce a machine which would successfully accomplish this service. In Fig. 9 is shown a sludge reduction machine, capable of reducing from 98 or less percentage of water to approximately 55 per cent, greatly facilitating the final disposition of handling or reworking of the sludge.

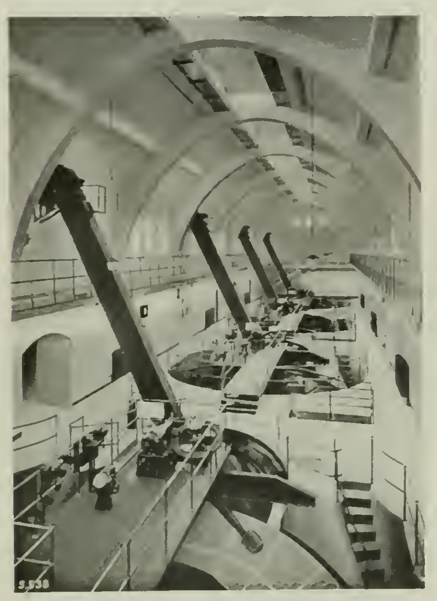

FIG. 7—INTERIOR OF DRESDEN SCREENING PLANT SHOWING FOUR RIENSCH-WURL SCREENS

The perfection and adaption of these machines renders the mechanical treatment of sewage entirely feasible and designs are now under way for a number of plants in the United States.

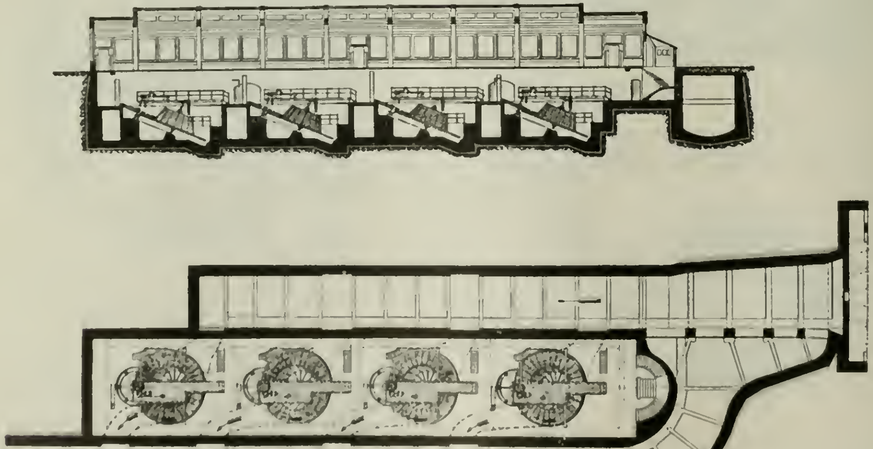

FIG. 8—PLAN OF DRESDEN SCREENING PLANT

The broader application of these screens in various industries should be appreciated with their growing use in the sewage disposal field. Wherever it is necessary to remove the solids from a large content of water, and where a process of screening is required, whereby the screening surface shall be continually kept clean and prevented from clogging the Riensch-Wurl screen should be found useful. Such industries as tanneries, slaughter houses, breweries, abattoirs, beet-sugar factories, pulp and paper mills, woolen mills, bleach works, and numerous other industries, should find in it, not only a simple method of recovering as a by-product, values formerly lost, but these industries would thereby be enabled to anticipate the growing demand for the protection of the streams by the clarification of the waste water from these industries before it is allowed to enter the waters.

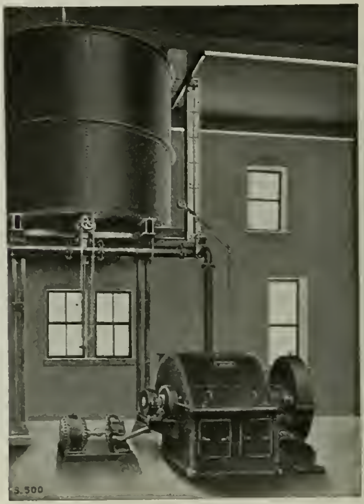

FIG. 9—D'OLIER SLUDGE REDUCTION MACHINE

## Apparatus for Determining the Hardness of Metals by the Brinell Method

The hardness can be determined in different ways. The simplest consists in cutting the metal to be tested by another metal or in determining the pressure which must be exerted on a diamond when cutting a smooth surface by passing it across the surface of the metal under test. Thus the file is often used to ascertain the hardness of steel.

However, these are distinctly laboratory methods; they require a well-polished surface and the use of the microscope, and are slow. Like the use of the file, moreover, they are not sufficiently reliable, the results depending on whether the file used is more or less blunt or sharp.

The Brinell method does not present any of these disadvantages. Brinell impresses a ball of hardened steel into the metal to be tested under a given pressure. He measures the diameter of the indentation made by the ball and determines the area of the spherical cup thus formed. By dividing the pressure exerted by the area he obtains what he calls the hardness number.

The same ball being pressed into different steels under the same unvarying pressure will embed itself to a different degree, thus determining in a regular manner the hardness of the piece. It is easy to read the impression of 1 mm by means of an ordinary magnifying glass, and one can say that each tenth corresponds to a given degree of hardness. The effect on the hardness of steels of different quenching agents for the same temperature, or for different temperatures, can thus be easily followed. It is even possible to determine the uniformity of a treatment by repeating the test in different places. Moreover, this test can be very quickly made—in less than one minute—on the finished product, without injuring same and without the necessity of making test pieces from the part.

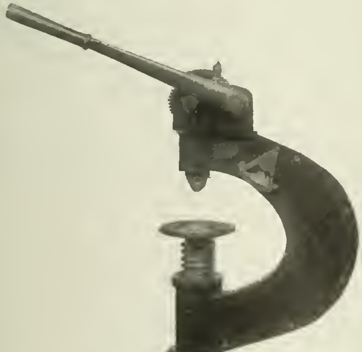

FIG. 1.—HARDNESS TESTING MACHINE READY FOR TEST

The advantage of the ball test is at least just as great when testing case-hardened pieces.

A very convenient apparatus for applying the Brinell method is the Derihon portable hardness testing machine, by which an impression is made with a 10-mm ball under a pressure of 3000 kgs.

Fig. 1 shows the machine ready for the test with the lever raised and resting on the shaft. The piece to be tested is placed on the table of the machine, which is then raised until the piece is in contact with the ball. This done, the lever is pulled slowly over so as to give a progressive pressure (the pressure is registered by a small manometer) until 3000 kgs are applied. When this figure is reached the lever is slowly returned to its former position and the test is completed.

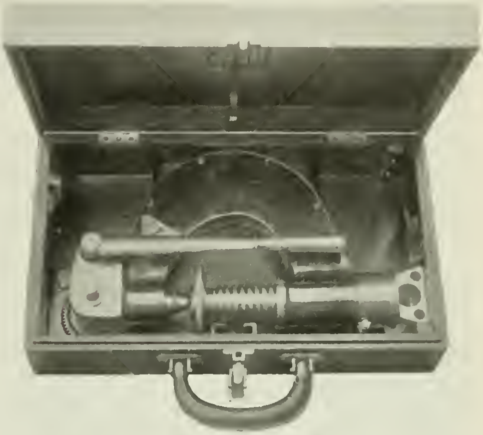

FIG. 2.—PORTABLE HARDNESS TESTING MACHINE

Under normal conditions it is usually sufficient to move the lever through an angle of 45 degrees to obtain the required pressure of 3000 kgs.

With each machine a small piece of steel is furnished in which a standard impression has been made, the size of the diameter being stamped on the same. This standard piece is of BND steel, an air-hardening chrome-nickel steel.

The accuracy of the machine can be easily controlled by making an impression alongside the standard impression.

The construction of the machine is based on the principle of elasticity of the frame, which for this purpose has been given the shape of a horseshoe.

The power produced by the pressure of the ball on the test piece has a tendency to open the frame to a certain degree in proportion to this power. The shape of the frame has therefore been specially considered in order to have it as elastic as possible.

The pressure exerted of 3000 kgs does not at all change the resistance or elasticity of the frame seeing that it is made of BND steel, having an elastic limit of 242,000 lbs. per sq. in., and that a pressure of 3000, 4000 or 5000 kgs does not work it above 10 kgs per sq. mm. (1442 lbs. per sq. in.). Under these conditions repeated tests even in large numbers do not alter at all the calibration of the machine.

The deflection of the frame being relatively weak (1 to 1.5 mm.), a register, the construction of which resembles a metal manometer, is installed in the hollowed-out part of the frame.

By means of a needle and a graduated dial the deflection and, therefore, the pressure exerted on making the test can be quickly and easily read.

To adjust the machine all that is necessary is to open the case enclosing the mechanism above the frame.

Should the machine ever get out of adjustment a comparison should be made on the standard piece, and when an impression of the same diameter has been made the needle is brought over the figure 3000 by means of a small adjusting screw.

This adjustment, however, would only be necessary through some accidental cause independent of the operation of the machine under normal usage.

Fig. 2 shows the machine packed in its portable case. This machine is placed on the market by H. A. Elliott, 507 Majestic Building, Detroit, Mich.

## Anti-Corrosion Pickling Chains and an Acid-Pump Casting

The life of forged chain used for handling material in pickling baths varies for the part submerged in or subjected to the action of the acid and fumes from eight days in the most exposed locations to a possible month under favorable conditions. Many methods of treating such chains have been tried out, but all externally applied protectors broke or wore off at the point of contact of the links, and added but little to the life of the chain.

TWIN-CYLINDER CASTING FOR ACID PUMP

Substitution of special acid metal chains for the iron ones was proposed, and found to give perfect satisfaction. Many of these chains have been in service for periods of from two to four years and have needed repair only when worn out.

Casting of such a chain offered many difficulties on account of the size, and the tendency for the links to cast solid. At the Morgan Engineering Co., Alliance, Ohio, where chains of this kind are now made, a four-quarter mold, built up of core sand and baked, has finally been designed. The alternate links were cast separately in ordinary molds and finished before being fitted into the molds for connecting, and the joining links cast around them. This method insures sound links and obviates the forming of blow holes found when it was attempted to cast the chain at one pouring.

The subjoining illustration shows a twin-cylinder casting for an acid pump made in the foundry of the same company. This casting is of unusual size and complexity and was the first of a lot of three pumps for handling large quantities of diluted acid and dirty water.

The casting required metal from three crucibles and when thoroughly cleaned up weighed 1680 pounds. No blow-holes or other irregularities were encountered in cleaning up the casting, and it was found that the metal averaged closely to the same analysis throughout, showing that the three meltings were the same and the heats similar. All the mechanism of the pump is to be of the same acid-resisting metal, preventing any damage to the pump through corrosion.

## Weighing and Regulating the Continuous Flow of Materials on Conveyors

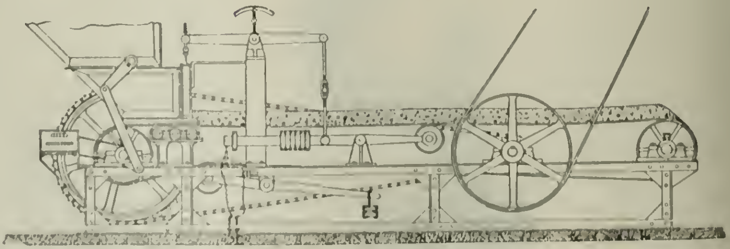
The adjoining illustration shows the Schaffer poidometer, built by the Schaffer Engineering & Equipment Company, of Tiffin, Ohio. This machine weighs and regulates the flow of materials traveling in a continuous stream over a conveyor. It can be attached to a hopper, bin or elevator spout, and delivers the material in any predetermined quantity at an even, regular flow, and records the amount handled, regardless of changes in specific gravity, amount of moisture or size of materials.

An interesting application of this machine which indicates the wide limits of its possibilities is in a clay products factory, where it adds manganese in proportion of one-half of 1 per cent and delivers the material at the rate of 2 lb. per minute.

The machine consists essentially of an endless belt traveling over pulleys and idlers similar to the method used in regular conveyors. One of these pulleys connects to the regulating and recording mechanism at the bottom of the containing bins.

In cases where it is desired to mix a number of different materials there is provided one machine for each of the materials, and each machine will deliver the desired proportions in a constant stream and insure an even mixture. This machine may also be used to advantage where moisture is to be added to materials in certain quantities.

When materials are put up in batches a special attachment is provided which controls the machine for any desired amount, and when the desired quantity has been delivered the machine automatically stops and again sets itself in operation at the proper time.



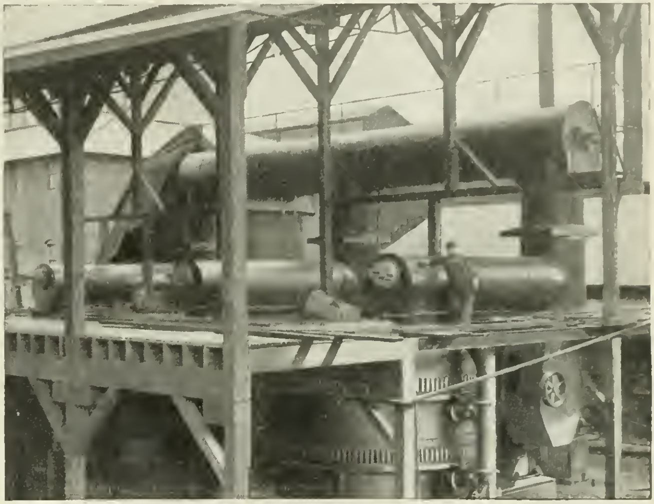
MACHINE FOR WEIGHING AND REGULATING THE CONTINUOUS FLOW OF MATERIALS ON CONVEYORS

The materials handled by this machine should be either in powdered or granular form, but a certain percentage of large lumps, up to 1¾-inch mesh, does not interfere with the proper performance.

## The Application of Producer Gas to Glass Factories

For the past two years the Chapman Engineering Company, of Mt. Vernon, Ohio, have been making a special study of the application of producer gas to the glass-making industry. The problem, viewed from a practical standpoint, presented two phases for study—the generation of a suitable gas and its proper combustion in the melting furnace. It became evident early in the investigation that efficiency in combustion was largely dependent upon a supply of gas uniform in quality and quantity. In other words, the gas producer was the vital factor in the problem, and in its correct design lay the real secret of successful use of producer gas in glass-making.

The demand for uniformity was met with their standard 10-ft. furnace-type producer. In this type fuel is fed continuously from a chamber so placed that it lets the fresh coal sink down on to the firebed, as the latter requires it, and in amounts exactly proportional to the needs of that part of the bed passing beneath the chamber at the time the coal is fed. The result is a perfectly leveled firebed at all times. In addition to this automatic leveling, uniformity of texture of the firebed through the body of the producer is obtained by means of a twisting action imparted to the firebed by revolving the upper and lower portions of the producer at different speeds. The function of this twisting effect is to close up incipient blow holes.



INSTALLATION OF THREE CHAPMAN GAS PRODUCERS

This method of feeding and agitation is radically different from the older schemes of intermittent firing, with consequent rush of gas immediately after each dumping of coal. Not only is the supply of gas from the Chapman producer uniform, but the quality is maintained constant.

Another feature which makes for uniformity is the continuous removal of the ash. This is accomplished by a device as ingenious as it is simple. The ash-removing mechanism includes an ash crusher, which grinds up the larger pieces of clinker that may be formed. The operation is entirely automatic, so that once it is set for the percentage of ash in the coal used it needs little attention beyond wheeling away the ejected ash.

Previous attempts to use producer gas for glass-making have met with much annoyance from the large amounts of soot which collected in the flues, and necessitated frequent shutdowns for removal. The Chapman Engineering Company attacked this problem from two points of view—repression and disposal during operation.

In the matter of repression, the small amount of soot is one of the features of the Chapman producer, which results from the unique method of fuel feed. The Chapman Company has originated a method of burning the soot in the flues without opening up the doors of the flues, as in the usual Sunday "burn-outs." This is done by means of an air blast introduced at regularly spaced intervals along the line of the flues. To a certain extent this method of soot elimination conserves the heat, otherwise lost, which results from the combustion of this much carbon (in the form of soot).

## Pneumatic-Type Recording Tachometer

The field of usefulness of recording tachometers is almost unlimited because there is a great need for measuring and controlling the revolutions of shafting, machinery, engines, etc. In some processes in mills it is desirable to have a certain speed or rate of revolutions maintained continuously or certain stops made periodically, but not too often, and the recording tachometer provides the superintendent or manager with information about the actual operating conditions maintained. For instance, blast-furnace blowing-engines are driven at a certain predetermined number of revolutions per minute, but are usually slowed up once every four hours at casting time.

Bristol's pneumatic-type recording tachometer has been developed to meet such requirements. It is now extensively used in connection with blast-furnace blowing engines for recording the speed of paper machines, etc.

In many instances it is not convenient to have a recording tachometer installed in self-contained form and located near the revolving shaft. One of the special features of the new Bristol pneumatic-type recording tachometer is the flexible connecting tube 25 ft. long or longer between the revolving mechanism and recording instrument which is mounted in any convenient position, as, for instance, on a switchboard or the wall of engine room.

The patent on this pneumatic recording tachometer was issued on July 30, 1912, to Prof. Wm. H. Bristol, and these tachometers, as shown complete in Fig. 1, have now been perfected for use under ordinary shop conditions. Some of the first models of this new tachometer have been in successful service for more than 2½ years.

The pneumatic principle of operation depends on the centrifugal action of air in a revolving tube which is connected on the recorder through a special oil seal and flexible connecting tube.

Fig. 2 shows diagrammatically the construction of the revolving mechanism. B designates a hollow circular protecting base and at its upper surface is provided a bearing for a hollow shaft D. This shaft is arranged to be rotated from any desired mechanism through a set of gears and pulleys (or sprockets).

A pulley C is shown over which a belt runs to a similar pulley attached to the shaft whose revolutions are to be measured and recorded. In practice most of these tachometers are being furnished with special form of sprocket and chain instead of pulley and belts.

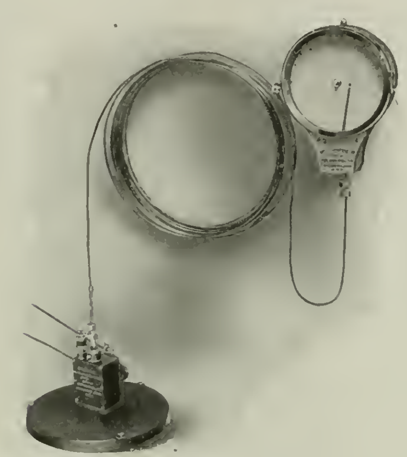


FIG. 1.—PNEUMATIC-TYPE RECORDING TACHOMETER

The lower end of the hollow shaft D, terminates in a horizontal tube A, open at its extremities. The upper end of the hollow shaft is surrounded by a casing E. It is partly filled with oil and into this extends the free end of another tube F. The tube F is stationary and is joined at its outer end to a flexible capillary connecting tube G, leading to the recording instrument.

The recorder used with this patented speed measuring device is a special low-range Bristol recording vacuum gauge. The recording instrument may be installed either near to or at a distance from the shaft or engine, the speed of which is to be recorded, and a suitable length of flexible copper tubing is furnished to connect the recorder with the revolving tube.

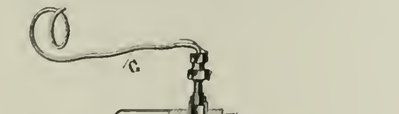

FIG. 2.—DETAILS OF REVOLVING MECHANISM

These tachometers are manufactured by the Bristol Company of Waterbury, Conn., who also manufacture electrical tachometers.

## Chart Recording Instrument

The Brown Instrument Company and the Keystone Electrical Instrument Company, of Philadelphia, Pa., are placing on the market a new continuous recording instrument for use as an electrical pyrometer for recording temperatures, and also as a recording voltmeter or ammeter. The clock mechanism is placed behind the record chart instead of to one side, and the record chart is the only part shown on the face of the instrument.

A two months' roll of record paper is used, which can be supplied with an ink ribbon to make a dotted ink record, or the record can be made on coated paper, which does away with the use of ink or ribbon entirely. It is only necessary to wind the clock once a week and change the roll of record paper once every two months.

Fig. 1 shows the instrument with a 10 hours' record on the recording chart. One scale is placed above the record so that the indications are clearly visible at all times, and the paper has the scale printed on it for direct reading. The instrument is shown with the door open so that the interior construction can be seen. This case need only be opened once every two months to renew the roll of paper.

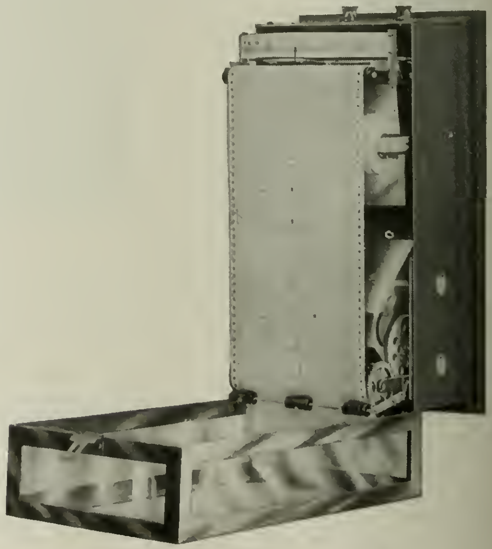

FIG. 1.—CHART RECORDING INSTRUMENT

This continuous recording instrument is intended to be used particularly as an electric pyrometer in conjunction with thermo-couples, or with resistance thermometers for measuring low temperatures, or for recording volts or amperes. The d'Arsonval type of direct-current instrument is used, of the frictionless type, to prevent lag in the readings and secure a sensitive and accurate instrument.

---

The El Ore Mining & Milling Company, of Elkton, Colo., state that weather conditions permitting they will start work on their new 300-ton milling plant about the middle of March, and invite correspondence from mining machinery manufacturers who may wish to take a contract on the building of the plant as a whole, or in part, according to the specifications which the company will be prepared to furnish to manufacturers or contractors.

## Electric Steel Melting

Mr. John A. Crowley, president of the John A. Crowley Company, of New York City, recently returned from England, having successfully concluded negotiations abroad for the exclusive representation of the Grönwall electric steel making furnace for this country.

The inventor is perhaps better known in this country in connection with the ore-smelting furnace of the same name which has had such noticeable success in smelting the Swedish ores, but his steel-melting and refining furnace has now been brought to a stage where it is being successfully operated in several of the English mills, and is also being introduced in the Sheffield section.

The Grönwall furnace is well adapted to either melting cold charges or refining from the molten metal as it is a two-phase type arc furnace with a neutral return fixed in the bottom of the furnace under the lining. Each phase of a two-phase circuit being connected to one of the vertical electrodes, which method forms independent arcs, insures a steadier running than if both arcs were in series, and noticeably reduces the instantaneous jump of the current from 50 per cent under load to 100 per cent over load, especially in melting from cold charges, and also produces a vertical as well as horizontal circulation in the metal bath. The neutral return is level with the brickwork at the bottom of the furnace and does not project or weaken the lining of the hearth, nor is the molten metal subject to any reaction on account of this neutral return. The electrical features of this furnace were described in detail and discussed in an article in our issue of November, 1911 (Vol. IX, p. 573).

The furnace is of the tilting type, permitting the withdrawing of the slag at any stage of the refining process and the introduction of another slag, and also permits the withdrawing of any part or all of the charge at any time.

The John A. Crowley Company will install one of these furnaces as soon as a suitable location can be secured. They will first aim at the production of higher grades of alloy steels for commercial purposes, but the production will not be entirely limited to this class of material, but will include the high-carbon tool and spring steels. Considerable attention will also be given to producing a high-grade steel for castings, for which line of work the furnace is particularly adapted.

## The Non-Ferrous Metal Market

The metal markets for copper, tin, lead and spelter have been without particular feature, and only slight changes have taken place in prices. Fluctuations in price have followed closely the changes in demand and while the tendency has been upward the higher prices have not always held in the face of lessened demand. Producers have been willing to make concessions and buyers have not taken more than enough to meet immediate needs.

**Copper.**—While the export market has been good the domestic demand has been variable. European stocks continue to decline in the face of heavy exports from this country. Local demand is considered to be improving slowly but steadily. Electrolytic copper is quoted at 14.60@14.70, and Lake at 14⅞@15⅛ cents.

**Tin.**—The tendency of prices in this market has been upward, and domestic demand has improved. A slight premium has obtained for immediate delivery.

**Lead.**—The American Smelting & Refining Co. raised its New York price to 4.15 cents on February 11, but reduced it again when the demand slackened. St. Louis lead prices have been above the New York parity. At last available reports the market has slumped decidedly, and New York lead is offered at 4 cents, with St. Louis at 3.90@3.92½ cents.

**Spelter.**—This market has been quiet, with a fair demand for metal. The tendency of prices is upward, New York spelter being quoted at 5.40@5.45 cents, and St. Louis at 5.25@5.30 cents.

**Other Metals.**—Business in aluminum has improved, but is still quiet. New York quotations are 18¾@19 cents per pound. Prices for antimony are firm and various brands are quoted at from 6 to 7.35 cents. Improvement also is noted in the quicksilver market, New York price being $39 per flask of 75 lb. San Francisco quotes $38.50 per flask.

## Personal

Dr. **F. G. Cottrell**, of the Bureau of Mines, has been engaged in the installation of apparatus for fume recovery at Anaconda.

Dr. **Rudolf Gahl** is making metallurgical investigations for the Inspiration Copper Company in Arizona.

Mr. **Ulysses A. Garred** has resigned his position at the Washoe smelter, Anaconda, Mont., and will go to Queensland where he will be with the Mount Morgan Gold Mining Co. He will be succeeded at Anaconda by Mr. **W. N. Tanner.**

Mr. **H. A. Guess**, formerly manager for the Federal Lead Co., Flat River, Mo., has been appointed consulting engineer for the American Smelting & Refining Co., with headquarters at 165 Broadway, New York City.

Mr. **H. W. Hardinge**, president of the Hardinge Conical Mill Company, has left New York for a six week's trip through Western mining centers.

Mr. **H. C. Hoover**, and his wife, **Lou Henry Hoover**, will be guests of honor at a dinner of the Mining & Metallurgical Society of America in New York City on March 9, at which time they will be presented with the Society's medal for their "Distinguished Contributions to the Literature of Mining."

Mr. **William F. Jahn** has been engaged as superintendent of the new cyanide mill of the New York & Honduras Rosario Mining Co., at San Juancito, Honduras, C. A.

Mr. **J. George Lehman**, vice-president and general manager of the Bethlehem Foundry & Machine Co., South Bethlehem, Pa., has just returned from a business trip abroad. Mr. Lehman spent some time in England and Continental Europe on matters pertaining to the development of acid-resisting iron, and while abroad closed a contract with the Lennox Foundry, of London, for the exclusive selling rights for Tantiron in the United States and Mexico. This acid-resisting metal has been in very successful use throughout Europe for a number of years.

Messrs. **Dorsey A. Lyon** and **Robert M. Keeney**, who have been stationed at the Pittsburgh laboratory of the Bureau of Mines, have been sent to Salt Lake City to start the cooperative federal-state work at the School of Mines of the University of Utah.

Mr. **Richard S. McCaffery** has been appointed professor of metallurgy in the University of Wisconsin. For the past few years he has held the position of professor of mining and metallurgy in the University of Idaho.

**Mr. H. P. MacGregor** has opened a laboratory for industrial and engineering chemistry at 535 First National Bank Building, in Denver, having recently severed his connection with Mariner & Hoskins, Chicago.

**Mr. Richard K. Meade**, Mechanical and Industrial Engineer, 202 North Calvert Street, Baltimore, Md., has just completed plans for a new coal pulverizing plant for the Pennsylvania Salt Manufacturing Co. This plant is designed to furnish coal for heating nodulizing furnaces. The plans call for a building of steel, 30 x 90 ft., and all the stairs, runways and galleries are to be of steel. No wood is to be used whatever in its construction. The equipment will consist of a dryer and two pulverizers, together with scales for weighing the coal, elevators, conveyors, etc. All the machinery will be motor-driven.

**Dr. Richard Moldenke** has resigned his position as secretary of the American Foundrymen's Association, but will continue to give his advice and assistance in editing the "Proceedings" of the Association.

**Mr. Richard A. Parker** has been elected president of the Colorado Scientific Society for the current year. Other officers elected were **E. N. Hawkins** and **T. B. Stearns**, vice-presidents; **John W. Richards**, treasurer; **H. C. Parmelee**, secretary; **J. D. Skinner, Charles A. Chase** and **Victor G. Hills**, members of the executive committee.

**Mr. George C. Piwonka** has resigned his position as general sales agent for the Western Chemical Manufacturing Co., Denver, Colo., and will engage in business in Cleveland, Ohio.

**Mr. B. Stanley Revett** is resident general manager of the consolidated dredging properties at Breckenridge, Colo., recently acquired by the Tonopah Mining Co. Mr. Revett was formerly manager for one of the companies that sold to the Tonopah concern.

**Mr. Carl J. Trauerman**, of the metallurgical firm of Rothwell & Trauerman, Butte, Mont., will take charge of the milling operations of the Bully Boy Co., Marysvale, Utah, after March 1.

**Mr. Guy M. Vail**, mining and metallurgical engineer of Portland, Ore., was in Denver recently on professional business.

**Mr. Archer E. Wheeler** has resigned his position as superintendent of the Boston & Montana Reduction Works of the Anaconda Copper Mining Co., to accept a position as consulting engineer to Union Minière de Haut Katanga, which has mining interests in Africa. **Mr. John H. Klepinger**, formerly assistant superintendent, succeeds Mr. Wheeler, and **Mr. Milo W. Krejci**, metallurgist for the company, has been named to succeed Mr. Klepinger.

**Mr. James Wood** has resigned his position as superintendent of the Calumet & Arizona smelter, and will no longer engage in active work.

---

**The sulphur output of Sicily** has shown a steady decrease during the past two working years, according to a recent Consular report. From August 1, 1912, to July 31, 1913, the total production was 351,752 tons, a decline of 15,489 tons, as compared with the previous year. The most striking decline in the exports is that to France, which has always been the best customer. This decline is believed to be due to the establishment of large sulphur refineries in France by the Union Sulphur Co. The Sicilian Sulphur Combine expresses the hope that the steady increase in consumption will permit the Sicilian industry to continue.

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

### REFINING METALS *(Concluded)*

669,442, March 5, 1901, Hans A. Frasch, of Hamilton, Canada.

Relates to the extraction of metals from metalliferous substances such as mattes, slags, ores, etc. The metalliferous material is suitably crushed and placed on the bottom of a tank where it is electrically connected as anode. Above this is placed a layer of sand as a diaphragm. An alkaline salt, such as sodium chlorid of 20° Baume strength is the electrolyte. Above the diaphragm are a plurality of cathodes. A plurality of tanks are connected so that the electrolyte flows from one to another in series. In the first and last tank, an overflow is provided from the anode compartment, and a separate overflow from the cathode compartment. In the intermediate tanks but one overflow, from the cathode compartment, is provided. The salt solution is supplied to the first tank and electrolysed, the overflow from the anode compartment passing to the intermediate tanks. In the cathode compartment of the first tank sodium hydroxid is formed, which is removed. In the intermediate and last tanks, copper is deposited from the circulating electrolyte. After leaving the last tank the electrolyte has been freed from copper, and of the remaining metals, iron is precipitated chemically, and the nickel, cobalt, etc., separated electrolytically.

679,824, August 6, 1901, Anson G. Betts, of Lansingburg, New York.

Relates to the electrolytic refining of crude lead, or "work-lead" containing such substances as gold, silver, copper, antimony, arsenic, sulphur, bismuth, nickel, iron, zinc and tin. This alloy is cast into an anode and electrolysed in a solution of about fifteen per cent lead fluosilicate and fluosilicic acid, together amounting to about twenty-five per cent of the solution. Such an electrolyte has a resistance of about two and two-tenths ohms per cubic inch. During electrolysis the electrolyte is circulated and the deposited lead is mechanically compressed from time to time, to break down sprouts and to present an even surface. When a sufficiently thick deposit is obtained, it is removed and melted. The cathode is preferably a sheet steel plate coated with lead.

684,049, October 8, 1901, Elmer G. Elliott and Valentine Kishner, of Perth Amboy, New Jersey.

Relates to apparatus used in refining metals. In practice the anode plates often come from the casting furnaces more or less distorted; also during operation some of the plates will bend or buckle. This invention consists in providing each tank with one or more series of insulating-pins which are mounted upon a movable support and connected to suitable manual operating devices. The pins are interposed between the plates where needed to mechanically separate them. The pins may vary in length and in location in the tanks.

687,800, December 3, 1901, Arthur L. Walker, of Perth Amboy, New Jersey.

Relates to a plant for electro-refining, and is an improvement in the conductors used to carry the current. It consists in placing a conductor plate or strip between two tanks, so that the cathodes of one tank and the anodes of the next are electrically connected. By this means the investment in conductors to carry the current from tank to tank is reduced at least eighty-three per cent over the former practice.

694,699, March 4, 1902, T. Ulke, of Sault Ste. Marie.

Relates to the refining of composite metals such as nickeliferous-copper material. In practice it is advantageous to use a material containing not less than twenty per cent nickel and eighty per cent copper, using a circulating electrolyte of sulphate of copper and nickel. During electrolysis, a certain amount of electrolyte is regularly withdrawn and replaced by copper sulphate solution. The copper deposit is by this means obtained under substantially uniform conditions. To the withdrawn solution is now added either ammonia or ammonium sulphate, thereby precipitating the nickel as nickel-ammonium sulphate crystals which may be purified by further crystallization. The nickel salts are then separately dissolved, the solution made alkaline with ammonia, and electrolysed. From time to time a portion of the impoverished electrolyte is withdrawn and used to precipitate the nickel crystals from the copper solution.

687,831, April 15, 1902, Hans A. Frasch, of Hamilton, Canada.

Relates to refining mattes, etc., and electrodepositing nickel. Refers to his prior patents 669,441 and 669,899. The apparatus preferably used is a series of tanks the bottom of which is covered with broken matte, etc., above which is placed a layer of sand to act as a diaphragm. A solution of sodium chlorid, 20° Baume, is added to the tanks until it comes through the sand diaphragm. Each tank has double inlet and outlet tubes, one of each below the diaphragm for the circulation of the anolyte, and one of each in the upper part above the diaphragm for the circulation of the catholyte. As catholyte, an ammoniacal solution of a nickel salt is used. The two solutions are circulated either continuously or intermittently. Nickel is deposited on the cathode, while the anolyte dissolves the metals in the matte, etc., as chlorides. The solutions do not mix with each other, the heavy chloride always remaining below the diaphragm.

713,277, November 11, 1902, Anson G. Betts, of Lansingburg, New York.

This patent was subsequently reissued as "Reissue 12,301." It relates to an improvement in the electrodeposition of lead by the process described in his earlier patent 679,824. The improvement consists in the addition of a reducing agent, such as gelatin, pyrogallol, resorcinol, saligenin, ortho-amido-phenol, hydroquinone, and sulphurous acid. Phenols of the aromatic series are well adapted for use in this process. It is preferred to use gelatin in the proportion of one part to about five thousand of solution. By the process the mechanical treatment of the lead described in the earlier patent is avoided, the deposited lead being compact and having a specific gravity of about 11.36. A current strength of ten to twenty amperes per square foot of cathode surface, and a corresponding E. M. F. of 0.15 to 0.35 volts for each element is used. With higher currents the lead becomes harder and more brittle.

713,278, November 11, 1902, Anson Gardner Betts, of Lansingburg, New York.

This patent was subsequently reissued as "Reissue 12,117." It relates to the refining of lead and refers to his prior patent No. 679,824. This patent has substantially the same subject-matter as the patent 713,277, but claims the product produced by the process claimed in 713,277.

714,861, December 2, 1902, David H. Browne, of Cleveland, Ohio, Assignor to The Canadian Copper Company, of Cleveland, Ohio, a Corporation of Ohio.

Relates to refining copper-nickel alloys. The material is cast into anodes, and part also into fragments; the latter put into a shot tower and treated with a current of chlorin gas and a shower of sodium chlorid. The fragments are dissolved, forming a solution of cuprous and nickel chlorids. This solution is passed through an electrolytic cell in which the copper is entirely removed, using the copper-nickel anodes and sheet metal cathodes. The outflowing nickel chlorid is treated with an alkali to precipitate the iron, leaving the nickel chlorid pure. This solution is now electrolysed, the chlorin evolved at the anode being used to treat the copper nickel fragments in the shot tower.

The nickel deposited upon the cathode is substantially pure.

---

## Book Reviews

**Chloride of Lime in Sanitation.** By **Albert H. Hooker**, Technical Director of the Hooker Electrochemical Company. Octavo (14½ x 22½ cm.), 231 pages; price $3.00. New York: John Wiley & Sons. London: Chapman & Hall, Limited.

The author acknowledges that Dr. L. H. Baekeland advised and inspired the writing of this work, which may be considered as a means of propaganda for sanitation in general and for the makers of bleaching powder in particular. Seven chapters describe respectively the manufacture and properties of the material in question, its uses for water purification, disinfection of sewage, street sprinkling and flushing, general sanitation (including use in epidemics), farm purposes, and killing the house fly. These occupy about one-third of the book, the other two-thirds being a compilation of abstracts and references on all of the above topics, either reproduced as a whole or carefully condensed. Mr. Hooker and his staff have made a timely and carefully-written contribution to an important branch of medical chemistry.

* * *

**Laboratory Experiments in General Chemistry.** By **H. B. North**, D.Sc., Associate Professor of Chemistry in Rutgers College. 12mo. (19 x 12½ cm.), 205 pages, 36 illustrations. Price, $1.00 net. New York: D. Van Nostrand Company.

This book describes 500 experiments, to be performed in connection with seeing a series of experimental chemical lectures, and using a good text book. From these, selections can be made suitable for varying classes of students. The experiments are excellently chosen, very clearly stated, necessary precautions to avoid danger given in italics, and attention called to the observations and conclusions in a manner calculated to sharpen the wits and educate the reasoning powers of the student.

The table of melting points of the elements needs up-to-date revision. The use of the atomic weights as whole numbers is to be commended in a work of this kind, as it avoids giving the student a fictitious idea of the quantitative accuracy of his experiments.

* * *

**Industrial Chemistry.** Edited by **Allen Rogers** and **Alfred B. Aubert**, in collaboration with thirty-four specialists. Large octavo 16 x24 cm.), xiv + 854 pages, 340 illustrations. Price $5.00 net. New York: D. Van Nostrand Company.

The volume is intended to represent American methods and processes, being an assemblage of the ideas of recognized authorities in their respective fields. Minor details have been given lesser attention. Theoretical considerations have been introduced only where necessary, but the subject matter is essentially descriptive, with most emphasis on the fundamental principles of the methods employed.

The contents embrace general processes, materials of construction, water supply, fuel, producer gas, boilers, engines, motors, power transmission, the common acids, commercial chemicals, chlorine industries, electrochemical industries (by W. S. Landis), lime, cement, plaster, clay, bricks, pottery, glass, white lead, pigments, oils, paints, iron and steel (by Bradley Stoughton), fertilizers, illuminating gas, coal tar and its products, the petroleum industry, distillation of wood, oils, fats, waxes, soaps, glycerine, candles, laundering, essential oils and perfumes, resins and gums, varnish, sugar, starch, glucose, dextrine, brewing and malting, wine, distilled liquors, textiles, dyes, paper, explosives, leather tanning, glue, gelatin, casein.

The treatment is very unequal; no chapters can be said to be poorly written, but some are much better than others—as was perhaps to be expected. Some important industrial chemicals are entirely omitted; hence the reason for cataloguing above the contents of the book. Such omissions are non-ferrous metals, refractory materials, celluloid, bakelite, enameling, treatment of sewage.

The book is beautifully printed and contains some very well written articles; it can be of great use to the student or manufacturer wishing to familiarize himself with the elements of industrial chemistry.

* * *

**The Electric Furnace:** Its Construction, Operation and Uses. By **Alfred Stansfield, D.Sc.,** Professor of Metallurgy in McGill University. Second Edition. Octavo (14 x 23 cm.), 415 pages, 155 illustrations; price $4.00 net. New York and London: McGraw-Hill Book Company, Inc.

Prof. Stansfield's second edition, revised, enlarged and reset, is practically a new book, and is, at the present moment, the best book in English on the electric furnace. It is very fittingly dedicated to Dr. Eugene Haanel, director of the Canadian Bureau of Mines, who has done so much towards starting electric smelting processes.

The details are carefully and systematically worked out. Particular mention should be made of the five chapters on zinc and on principles of construction and operation. The latter makes use of the recently published data concerning heat conductance of furnace walls and electrodes, and is admirably written. In fact, there is scarcely a chapter in the book which does not deserve commendation.

One disappointment is the bare mention of the "large number" of electric furnaces which have been devised for the manufacture of glass, without any description whatever of these interesting furnaces. Bronn, in *Die elektrische Oefen*, gives a large part of his work to them. The book is suitable alike for students, technologists and the general scientific reader. We congratulate the author on the very useful result of his scholarly and conscientious work.

* * *

**Quantitative Analysis by Electrolysis.**. By A. Classen, with the cooperation of **H. Cloeren.** Translated from the fifth German edition by **Wm. T. Hall,** Assistant Professor, Massachusetts Institute of Technology. Octavo (14 x $22\frac{1}{2}$ cm.), xiv + 308 pages, 51 figures, 2 plates; price $2.50 net. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd.

The present edition may be regarded as practically a new book, since it contains all the improvements in the theory and practice of electro-analysis made in the last decade. The translator has added to the original the Spear and Strahan rapid method of determining zinc. He also uses the notation and symbols recommended by a committee of the American Chemical Society. The skilled electro-analyst will find collected here all the reliable information extant, while the general reader will be astonished at the versatility and applicability of electro-analytical methods. Further yet, the electro-chemist interested in electro-plating, electro-extraction or electro-refining of metals will find therein many items of exact and useful information directly applicable to the problems which he is trying to solve.

* * *

**Electrical Engineering for Mechanical and Mining Engineers.** By **H. J. S. Heather, B.A.** Octavo 13 x 21 cm.), ix + 332 pages, 184 illustrations; price, $3.50 net (9/6d). New York: D. Van Nostrand Company. London: "The Electrician" Printing and Publishing Company, Ltd.

This book contains a series of twenty lectures prepared for and delivered to the resident mechanical engineers of the mines of the Witwaterswand, South Africa. The author was at that time connected with the University of the Cape of Good Hope and the South African School of Mines and Technology.

No attempt was made to impart a general knowledge of electrical engineering, but the lectures were intended to give to the mechanical engineers at the mines the elements of electrotechnics, so that they would be able to understand or possibly to supervise the work of the mine electrician. Any non-electrical engineer wishing to get an intelligent idea of the principles of electrotechnics and of the elements of electrical engineering will find this book helpful and useful.

* * *

**Die Quantitativen Untersuchungsmethoden des Molybdans, Vanadiums und Wolframs.** By **Dr. Hans Mennicke,** Ing. Chem. Six by 10 inches (18 x $25\frac{1}{2}$ cm.), 231 pages. Price, paper, Mk. 8; bound, Mk. 9.50. Berlin: M. Krayn.

Under this title appears a collection of practically all the analytical work along these lines. The methods of analysis are set forth in the order of their importance, based on the accuracy of the results obtained therewith, and on their commercial applicability.

The subject is treated under four heads: (A) introductory; (B) Molybdenum; (C) Vanadium; and (D) Tungsten. The introductory part describes the determination of carbon and sulphur in metals, ferro-alloys, and special steels containing these rare metals. An appendix gives the literature and a factor table.

The three main subjects are treated accurately and satisfactorily. They are properly subdivided, and special stress is put on indicating the work of greatest value for accurate determinations. The methods of analysis of importance are clearly described in detail and one feels that among them may be found methods applicable to any special cases occurring in the analytical, chemical and metallurgical field of these rare metals.

The book is of value as a guide not only to the student interested in the chemistry of the rare metals, but also to the practical man handling the raw or finished products containing molybdenum, vanadium, or tungsten as a constituent, such as ores, salts and preparations, alloys and steels. As the literature on the rare metals is somewhat scattered, this collective work on the subject treated is probably better than anything in print in the English language.

---

**Suit for dissolution** of the American Smelting & Refining Co., under the Sherman act, is being considered by the Department of Justice.

The **Richmond Forgings Corporation,** of Richmond, Va., makers of drop forgings, has opened an office at Detroit, Mich., which for the present will be in charge of Sales Manager Landon C. Wellford, in the Dime Bank Building. Mr. A. O. Knudsen, of Newton Centre, Boston, Mass., will represent the same company in the New England States.

## Central Research Organizations

Research is the order of the day in metallurgy. The time was when companies moved along in an even tenor, more satisfied than dissatisfied with their processes, showing little disposition to look for improvements or new ideas as long as they met with financial success. They limited their operations to the treatment of ores readily amenable to comparatively simple processes, and took the cream of mineral production. The number of technically trained men was small, and operations were conducted more by rule-of-thumb. Such were the conditions that inevitably surrounded the inception of the metallurgical industry in the West.

Development in the arts, sciences and technology has been accompanied by a vast increase in the number of trained workers who have the spirit of investigation demanded by the intricate problems that have come hand in hand with the change in economic conditions. To-day no concern of importance rests on its laurels. Research departments are maintained in various degrees of magnitude. Appropriations from earnings are regularly made for the support of investigation. Methods of operation change so rapidly that one is kept busy if he would be in touch with developments from month to month.

All of this represents a state of healthy discontent, and contributes greatly to progress. But the question arises: Is metallurgical research being conducted to the greatest economic advantage? Is progress as rapid under a system in which each company maintains its corps of workers, as it would be if groups of companies engaged in similar pursuits supported a central research organization? Instances could be cited which apparently warrant an answer in the negative, though there is no thought of suggesting that the idea is of universal application.

Consider, for example, the research work of the established copper companies. A half dozen could be promptly named that are investigating hydrometalurgical and other processes of common interest. Not forgetting that each problem is in some measure peculiar to itself, we presume there must be some fundamental features common to all, which, once solved, would be of general benefit. And yet each investigator is working individually on the same problem. Not only is a great deal of work needlessly duplicated, but time and money are consumed without profit. Perhaps several men carry on investigations to the same point and then abandon them. Later, another investigator, not fully informed, repeats all the work and ends at the same point instead of taking advantage of previous work and starting where others stopped.

Of course, the usual objection to centrally organized research is found in individual ambition and professional jalousy. Each wants credit for his work, and fears to lose his identity in a larger scheme. But there might be just as much pride in belonging to a fine organization as in working alone, and the economic results ought to be greater. Even under present conditions there is willingness to "swap ideas," and representatives of the large companies are constantly visiting back and forth, so that some degree of benefit accrues from the interchange of knowledge. But even so, there is much duplication of work and unproductive experimenting for which the industry pays several times instead of once. Separate research departments have proved valuable. May not central organizations be the next economic step?

### Aesop at Niagara Falls

Our friend the *Mining and Scientific Press* of San Francisco, writes as follows:

"Much as we admire our brilliant contemporary, *Metallurgical and Chemical Engineering*, we cannot accompany it on its forays into the realms of natural history. Recently it sought to illustrate the present situation at Niagara Falls by means of a fable in which a beaver and an eagle enter into an agreement to divide the fish they catch, an arrangement which worked admirably until a tiger appeared and demanded a share of the spoil. Possibly the metamorphoses effected by the metropolitan fur dealers, who without difficulty transmute a raccoon into a Hudson seal, have so bewildered the New York editor that he confuses a beaver with an otter and an eagle with an osprey, but where does the tiger come in? Fortunately Mr. Theodore Roosevelt is still in South America and the life of the nature-faking chemical engineer is therefore not in immediate danger, but we advise him to accept an engagement which will take him to the Lena goldfields, or some equally inaccessible place, at the earliest possible moment."

We have heard of a fox with an appetite for grapes; but East is East and West is West, and fish stories are not understood by some people.

### The Steel Corporation's Report

The United States Steel Corporation began business April 1, 1901, so that the report for 1913, just issued, covers its twelfth full calendar year. The 1913 earnings, $137,181,345, make the best showing for a year with but three exceptions, 1906, 1907 and 1910. The tonnage of steel products measured in the form in which sold, 12,374,838 tons, stands second to that of but one year, 1912, and is only 1 per cent below the total for that year. The earnings per ton in 1913, $11.09, are naturally less than in any of the three years in which total earnings were larger. They are indeed smaller than those of eight of the twelve years, viz., 1902, 1903, 1905, 1906, 1907, 1908, 1909, and 1910, and they exceed those of 1911 by only 8 cents.

Thus the Steel Corporation has in its twelve years of life somewhat increased its total earnings, while it has greatly increased its tonnage, and its earnings per ton have very materially decreased. In its last three years its total earnings have been materially greater than in its first three years.

There was a remarkable increase in the Steel Corporation's labor cost in 1913. The comparative figures are as follows:

| | 1912 | 1913 |
|---|---|---|
| Average number of employees | 221,025 | 228,906 |
| Total salaries and wages.... | $189,351,602 | $207,206,176 |
| Average per employee per day: | | |
| Excluding general administrative and selling force ........................ | $2.68 | $2.85 |
| Including general administrative and selling force ........................ | 2.75 | 2.92 |

The total output decreased from 1912 to 1913 by about 1 per cent. Furthermore, the output of sheets and tinplates decreased from 12.8 per cent of the total to 10.3 per cent of the total. Of the important branches, this is the one which employs the largest number of men per ton of output, and of the number employed a large proportion are highly paid tonnage men. It is, therefore, remarkable that the total number of employees increased by 3.57 per cent. The larger increase in total wages and salaries paid, 9.43 per cent, reflects the general wage advance made effective Feb. 1, 1913, which affected about 75 per cent of all employees, giving them advances ranging from 12½ per cent in the case of the lower paid men down to smaller percentages for higher paid men.

Inasmuch as the average degree of finish of the Corporation's output has increased, trustworthy comparisons cannot be made, but it is interesting to note that its apparent wage and salary cost, per ton of output in the form in which sold, was $14.94 in 1902 and $16.76 in 1913, an increase of 12 per cent. Meanwhile the average pay per man increased 26 per cent. Having regard to the higher degree of finish attained in the average ton of product, the manual effort per ton has probably decreased, but only slightly. The remuneration in proportion to effort has probably increased considerably. It is quite possible that the increase in wages received has not fully equaled the increase in the cost of living, but there is the very important fact that the average selling prices of steel have greatly decreased since 1902. Realized prices upon steel were very much lower in 1913 than in 1902. The margin per ton of output has decreased, but interest and dividend payments have been maintained through the production of a larger tonnage.

### Engineering Education

The recent announcement that Harvard University and the Massachusetts Institute of Technology have arranged to combine their forces in support of engineering education, may have a broad bearing on the future of engineering schools in this country. It suggests a tendency toward consolidation or concentration of educational forces, rather than further division and duplication. Universities and colleges are not efficient institutions when regarded from a business point of view. There is too much duplication of plant and staff, frequently accompanied by insufficient resources to make the work effective. This results in a struggle for existence that handicaps the institution and its students.

With this entering wedge already made in the East, it is likely that its effect will gradually be felt in the West and cause a much needed readjustment among western schools. The State largely supports university and college education in the West. In some of the commonwealths there has been a deplorable duplication of work, that puts a needless burden of taxation on the citizens. Colorado, for example, has a State University, School of Mines and Agricultural College, each teaching some branches of engineering. Washington has a State University and State College; Utah, a State University and Agricultural College; Oregon and Montana each maintain two, or, possibly, more, separate institutions, and so on through the list.

In all of these States the legislatures are called upon to appropriate funds for the maintenance and extension of two or more schools; and it seems inevitable that, from purely economic considerations, consolidation and concentration of effort will be forced on western schools. At present there is needless duplication in administration, instruction and equipment, and each institution is constantly, and quite naturally, increasing its demands on the State. The cost of education per student is needlessly high, for attendance is divided and equipment is multiplied.

The example furnished by Harvard and Technology probably will bear fruit elsewhere, East as well as West. From the larger point of view, the idea of consolidation is excellent, even though it entails sacrifice of individuality. The results ought to be a higher standard of engineering and a greater efficiency among future engineers. If western schools can agree on a scheme for cooperation they will have the satisfaction of working out their own salvation instead of having it forced upon them.

## The Changing Character of Rail Steel

A few years ago it became evident that the ordinary Bessemer steel rail was doomed. The statistics of rail production in 1913, made public within the past fortnight, furnish conclusive evidence that alloy-cleared Bessemer steel has so far failed to save the situation for Bessemer steel. It still remains to be seen whether the electric refining process may not save the Bessemer rail. The electric steel rails at present in track have stood very well so far, but it would seem that some reduction in cost of the electric treatment was needed to encourage the railroad companies to become buyers.

In 1909 it became clearly established that the plain Bessemer rail could not survive as anything more than a subsidiary product. In 1907 the proportion of Bessemer to total steel rails was 93 per cent; in 1908 it was 70.3 per cent, and in 1909 it was 58.5 per cent, showing a rapid and irresistible trend. In 1912 the proportion was 34.4 per cent, while in 1913 it had dropped to the almost negligible proportion of 24.4 per cent.

The decadence is still more emphatically shown by the observation that of rails weighing 85 lb. and over per yard the proportion of Bessemer in 1913 was only 12.2 per cent. The standard rail of the future, of course, promises to weigh more than 100 lb. rather than less.

As to alloy-treated steel rails the following statistics of production in gross tons are very illuminating:

| | Open-hearth. | Bessemer. | Total. |
|---|---|---|---|
| 1909 | 13,696 | 35,699 | 49,395 |
| 1910 | 27,389 | 229,935 | 257,324 |
| 1911 | 38,539 | 115,450 | 153,989 |
| 1912 | 40,393 | 108,874 | 149,267 |
| 1913 | 33,567 | 25,952 | 59,519 |

The total of alloy rails was a maximum in 1910, there being a rapid decrease whereby three years later the quantity of such special rails was diminished to less than one-fourth of the 1910 total. Of additional significance is this fact, that while in 1910 practically nine-tenths of the rails alloyed or titanium treated were Bessemer, in 1913 less than one-half of the greatly diminished quantity was Bessemer.

The regular alloy rails are given as manganese, copper and nickel, electric rails being included in the statistics whether alloyed or not. In 1909 there were 35,945 tons titanium-treated, but the statistics do not show the division between Bessemer and open-hearth. Beginning with 1910 the titanium rails are shown separately as to Bessemer and open-hearth, and the figures again show a strong decline for Bessemer rails.

Within a few years the possibility of reviving the Bessemer rail by the discovery of a new process will have been greatly reduced, because the Bessemer equipment, which originally involved the expenditure of millions of dollars, is itself disappearing. One by one the great Bessemer steel plants have been modified, by actually dismantling the converters, by resorting to duplexing, or by the addition of open-hearth furnaces which would supply at least part of the steel for the attendant rolling mills. The last to yield has been the great Edgar Thomson works in the Pittsburgh district, in which plant fourteen large open-hearth furnaces have been installed in the past year.

Last year's total rail production was 3,502,780 tons. While this showed a gain of 5.2 per cent over the previous year, there were three years, 1906, 1907 and 1910, which showed a larger production than 1913, and the largest year of all was 1906, with 3,997,887 tons. Thus in seven years the rail industry has failed to make a new tonnage record. Such a lapse is not a new thing in rail manufacture, for in 1887 there was produced 2,139,640 tons, and it was not until 1899, twelve years later, that a new record was made.

Even the export trade in rails does not make a particularly good showing. It is true, 1913 made a new record, with 460,553 tons to its credit, but as long ago as 1900 there was exported 361,619 tons. Included in the 1913 exports was 161,971 tons shipped to Canada, against only 25,341 tons in 1910.

Rail exports apart from Canadian have really decreased in the most recent years, and it is fairly plain that very large exports to Canada cannot be continued. Canada is building railroads at a rapid rate for the moment, but the demand is probably temporary and it is doubtless for that reason that Canada does not establish sufficient rail-making capacity of her own to supply the demand.

### Quotations from Classics

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—It grieves me very much to feel compelled to criticise Mr. Woolsey McA. Johnson's article in the current number of your journal. On page 167 Mr. Johnson makes a grossly inaccurate quotation from that great English classic, "Alice Through the Looking Glass." While I fully realize the difficulty of making correct quotations from memory and while errors may be excusable in the case of relatively obscure and inaccessible literature, I fear that if something is not done your pages will shortly be disfigured by incorrect quotations from Shakespeare and the Bible.

Francis A. J. FitzGerald.

*Niagara Falls, N. Y.*

* * *

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—I have read Mr. FitzGerald's letter. I could have wished that he criticise the article in more important parts. The quotation is as follows:

"The walrus and the carpenter were walking close at hand. They wept like anything to see such quantities of sand. If this were only cleared away, they said it would be grand."

"If seven maids with seven mops swept it for half a year, 'do you suppose,' the walrus said, 'that they could get it clear?' "

My use of the above was, of course, merely in nature of a paraphrase and no pretence to accuracy was made.

Woolsey McA. Johnson.

Hartford, Conn.

### Keeping an Electric Furnace Hot During Periods of Idleness

*To the Editor of Metallurgical and Chemical Engineering:*

Sir:—In my article on the Stassano electric steel furnace at Redondo, Cal., in the December, 1913, issue of this magazine, it was stated that another furnace of the same type was being built in an Eastern foundry. This latter furnace has been in operation for some time at the works of the Hess Steel Castings Co., of Bridgeton, N. J., and results equally as good as at the previous installation are reported.

The furnace is an exact duplication of the one running in California, and we refer to the description and pictures of it in the above-named article in the December issue.

One new and economic feature in the operation of the furnace, however, is of especial interest. Slackness in business made it possible to turn out only one heat per day, and for some time only one heat every other day. The question arose how to keep the basic magnesite lining hot during the long intervals at a minimum expense.

Heretofore the Stassano furnaces running in daytime only have been kept hot nights and during the Sunday idleness by electricity, which method involved a considerable expense for current, electrodes, and labor. In this new installation, however, an arrangement was made to keep the furnace hot by means of an oil burner, cutting down the cost to a small fraction of the former cost for electricity, and entirely eliminating the cost of electrodes and labor, as the oil burner needs no attention whatever. A similar arrangement has been worked out independently for the California furnace.

The small steel foundries, which could not take care of the total output of five tons for 24 hours of the one-ton type of Stassano furnace, or which for some other reason wanted to avoid working a night shift, will be highly interested in the fact that they can now run a furnace of this type in daytime only with two or three heats, at only a nominal expense for heating. In many instances the foundry gains the added advantage of keeping off the peak load of the power company supplying the current, and thereby enjoying a cheaper current rate.

Ernest M. Schmelz.

Detroit, Mich.

### Efficiency and Refining Possibilities of the Induction Furnace

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In your February issue, page 74, Mr. Ivar Rennerfelt is good enough to draw my attention to the fact that the original statement in my article "Induction Furnace Notes" of October, 1913, was correct and not an error as stated in the December issue, 1913.

As Mr. Rennerfelt assumes, the expressions "melting hours" and "kilowatt hours" (units) have been mixed up, as I find by looking up the melting records. I, therefore, wish to thank Mr. Rennerfelt for drawing my attention to the mistake.

An *electric* efficiency of 67.1 per cent, however, is certainly not unattainable in a two-ton furnace; I have on record an efficiency of well over 71 per cent in an even smaller furnace having a capacity of only 850 kg.

But it should be borne in mind that the expression "electrical" or "theoretical" efficiency is a very deceiving one.

As is well known generally, steel is not made by simply melting down scrap; even at its best it must also be purified from gases, oxides, etc., and the figure of 63.8 per cent includes all power spent for such purposes.

The *economical* efficiency is, to my mind, the only important factor, as is also emphasized in the subsequent paragraph of the article.

As to the refining question, it is well known and has often been repeated both by myself and others that the *single-ring* induction furnace, with its narrow channel and small bath surface, is not intended to be used for the removal of sulphur and phosphorus, but in many respects it is an ideal melting furnace and is therefore recommended as such.

It was this I had in mind when the statements quoted were made.

The "combination" induction furnace of the Rodenhauser type, however, to which Mr. C. H. Vom Baur no doubt was referring in his article, and which I also have had many opportunities to watch, has very good refining possibilities on account of its enlarged central hearth and larger bath-surface.

So has also the double-ring induction furnace designed by Mr. O. Frick.

It is not my intention to enter into a controversy as to the relative merits or disadvantages of arc furnaces and induction furnaces; both have their fields and if one is asked to recommend one or the other, as is frequently the case, the answer must be made solely with the purpose in view for which the furnace is intended, disregarding any sentiment in favor of one or the other.

Special conditions, as regards the work to be carried out, the locality, the available electricity supply, the question of continuous or intermittent operation, etc., must be carefully considered in each individual case before one is able to recommend one system or the other.

An open discussion, such as Mr. Rennerfelt suggests, would no doubt be of general interest. But it is very questionable whether it would lead to any so-called final decision. Both systems will no doubt continue to live side by side, as past experience seems to indicate.

Only the most careful consideration of each individual case and a full knowledge of the merits and possibilities, as well as the drawbacks and limitations of the various furnace types, will enable the engineer and metallurgist to make up his mind which type is most likely to be successful in his particular case. JOH. HARDEN.

Luton, England.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—Mr. Rennerfelt's communication appearing in your February issue is very interesting. No doubt what Mr. Harden had reference to was a single-ring induction furnace of the Kjellin type. My own experience with furnaces of this kind has confirmed that it is impractical to endeavor to refine steel with the usual slags in a single-ring and narrow-channeled induction furnace.

However, all these furnaces had to have their beginning, and it is now over a dozen years ago that Kjellin first placed an induction furnace in regular commercial operation. It is now over seven years that the first wide-hearthed induction furnace was placed in operation, and one is now under construction with a bath the exact proportions of an open-hearth of corresponding size. The induction furnace will soon be in its early manhood, with the progress now going on.

To return to the refining—as soon as a two-ring induction furnace was placed into practical operation, it was demonstrated that any degree of refining of phosphorus and sulphur and general degasification could be obtained. A curve taken from Rodenhauser's and Schoenawa's book on Electric Furnaces in the Iron and Steel Industry, page 399, shows that the phosphorus dropped from 0.06 to 0.025 per cent. in the first 20 minutes, while the desulphurization was from 0.065 per cent. to traces in somewhat more than an hour. The general deoxidation or degasification is exemplified by the excellent physical qualities of tool steel—about 57 varieties—not to mention rail steel and others, made in the 8 to 10-ton Roechling-Rodenhauser furnace, charged with liquid basic Bessemer steel.

There are as many induction furnaces to-day in Germany as there are arc furnaces, so that favoritism is at least evenly divided, even though the induction-furnace installations are usually more expensive for the same size, than their arc-furnace brothers.

At Kladno, the Poldhihuette after using a 4-ton Kjellin furnace, single-ring type, for about 6 years is installing an improved design of induction furnace of 13 tons capacity. One of the large iron works of Eastern Pennsylvania is installing two 20-ton induction furnaces. Krupp at Essen has two 10-ton induction furnaces in regular operation, so whatever their "practical drawbacks" are, their virtues are enough to overcome them as the repeat orders indicate. The induction furnace is a very rugged child in the electro-metallurgical industry just now, even though it was a little dwarfed in its infancy.

C. H. VOM BAUR.

Douglaston, N. Y.

## Concentration of Complex Sulphide Ore from the Mary Murphy Mine

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—In the issue of your magazine for March, 1914, page 157, Mr. Dyke V. Keedy has contributed a rather elaborate discussion on the concentration of complex ore from the Mary Murphy mine, based on my original article on the same subject in your January issue. It is personally gratifying to think that Mr. Keedy should have analyzed the article in such detail, but it seems to me that he set for himself a laborious task, the results of which are of little or no value, due to the fact that he draws conclusions from incomplete data and from assumptions of his own. That the data were incomplete is scarcely a legitimate criticism of the original article, for it was not an engineering report on the efficiency of the Mary Murphy mill, based on a related series of tests and investigations, but a description of operations by a visitor, with occasional figures and tabulations to show the results obtained. There is every reason to believe the general accuracy of the data given; but it is obvious that the figures were not such as would justify an attempt to make the checks and calculations submitted by Mr. Keedy. As a consequence, the fallacy of much of his contribution lies in the assumptions he has made and substituted for unstated facts.

In the first place, the weights of products (lead concentrates, zinc-iron middlings and zinc slimes) are not actual net dry weights, but the total of daily estimates made by the mill operatives on moist products, which estimates usually are well on the safe side. As a matter of fact, the actual shipments of lead concentrates credited to September operations totalled 161.62 tons, as against the daily estimates of 138 tons. The estimated tonnage should not be used in such calculations as Mr. Keedy has made, and probably he would have been spared his trouble if I had explained them more fully. Being merely estimates taken from the daily operating sheets, they might properly have been omitted. Since the weights of recovered products are not accurate, the assumed weight of tailing also is inaccurate, being estimated by difference; and the re-calculated recoveries cannot stand, being based on assumptions. Furthermore, in calculating the gold recovery Mr. Keedy assumes all amalgam as gold, thereby making even his reduced saving too high.

The method of calculating recoveries from head and tailing samples is criticized as "incorrect and misleading because of the very important fact that the large quantity of water used on the jigs and tables, and running to waste therefrom, carries unseen and frequently unnoticed an unknown quantity of mineral values." At the Mary Murphy mill the tailings from all concentrators are combined before leaving the plant, so that a fair sample of general tailing is taken. The quantity and value of suspended matter in the tailing water, escaping collection, is not as great as one would think, especially if some precaution is taken to assist settlement in the sample. Thus, on one occasion, 500 lb. of water was decanted from a settled tailing sample and evaporated to dryness. Only 2 oz. dry slime, or 0.025 per cent., was recovered, containing a trace of gold, 1.4 oz. silver per ton, 4 per cent. lead and 18.7 per cent. zinc. When one remembers the ratio of water to solids in tailing, about 15 to 1 in this case, the loss in suspended matter is seen to be inconsiderable, and a tailing sample prepared in this way forms a good basis from which, together with products, to calculate recovery.

Mr. Keedy prefers to omit from zinc and lead "recoveries" that portion of those metals contained in lead and zinc concentrates, respectively, because he says they bring no economic return and may even entail penalties. I think he understood, however, that the "recovery" figures I gave represent metallurgical saving and not economic recovery. A knowledge of the smelter contracts on the various products would be necessary to determine economic recoveries and losses, as well as possible penalties. Unquestionably loss is suffered, but it cannot be determined by assumptions. It is generally recognized that metallurgical saving and economic recovery on such an ore are not synonymous.

In regard to the electrostatic work, the failure to give weights of products in my tabulations is an omission, for they were placed at my disposal. Mr. Keedy is quite right in assuming that the assayer's figures are reliable, but he falls into a pardonable error in attempting to check up the gold in the various products from Mary Murphy ore. Weights would have been of little value in such an effort, and might have made the problem more perplexing. It is my understanding that close accounting for gold is considered one of the impossibilities at the Mary Murphy; in the mine, in the mill, and almost equally in the smelter settlements, it is strictly where you find it, and not always where it ought to be. Referring to the retreatment of electrostatic middlings, which Mr. Keedy says "resulted in a net loss," I will say that the table of figures was given for the very purpose of showing how unsatisfactory the experiment proved.

Touching on the criticism of the regrinding practice. Mr. Keedy's suggestion to by-pass the slime contained in tube mill feed is perhaps pertinent. But in objecting to too-fine grinding of the entire pulp he must not forget that the character of Mary Murphy ore is such that fine grinding is required to liberate gold, even though base minerals are slimed in the operation. It is a question of economic operation. I presume that the management of the Mary Murphy is cognizant of the value of gradual reduction in size, in concentrating such an ore. Perhaps a few months' experience at the mill would reveal to Mr. Keedy many practical difficulties which cannot be appreciated otherwise. A clearer insight to the situation will be gained by reading an article by Mr. George E. Collins, manager for the Mary Murphy company on page 243 of this issue. It furnishes many interesting details relating to the mill practice.

Denver, Colo. H. C. Parmelee.

## Pyrophoric Alloy Patent Decision

In the suit of the Treibacher Chemische Werke (Gesellschaft mit Beschränkter Haftung) vs. The Roessler & Hasslacher Chemical Company, a decision has just been rendered in the District Court of the United States, Southern District of New York. The decision which is written by Judge Hough is in favor of the complainant. The patent in question, No. 837,017, issued to Welsbach on Nov. 27, 1906, and assigned to the Treibacher Chemische Werke, is held to be valid as a pioneer patent and to be infringed.

From Judge Hough's decision we quote the following:

"The only claim involved is this: 'A pyrophoric alloy, containing cerium, alloyed with iron; substantially as and for the purposes described.'

"The 'purposes described' in the specification render plain the contest before the court.

"The patentee tells the world that all preceding investigators were wrong in supposing that the so-called 'rare-earth' metals, when pure, possessed pyrophoric capacity, i.e., the property when abraded of giving off particles self-igniting in the air.

"Admittedly these metals, and especially cerium, had long been called pyrophoric, but Welsbach deems himself the first to discover that the spark-giving quality depended on impurities whose presence had before him been unobserved, or if noted considered negligible.

"It is not pretended that this ascertainment of a natural phenomenon constitutes patentable invention.

"Since, however, the cerium ordinarily obtainable had been known to give forth sparks and abrasion, Welsbach says he sought to ascertain what kind of mixture would produce sparks in greatest abundance. Iron afforded the best results, and an alloy of cerium 70 per cent and iron 30 per cent the maximum pyrophoric effect.

"The sparks elicited are not different from those known to have been drawn from the 'rare-earth' metals as produced from Welsbach's experiments, but the flow from his alloy is said to be so copious and certain as to furnish a 'prompt and reliable' means of igniting 'combustible gases mixed with air.'

"The patentee experimented with 'certain other metals,' and mentions nickel and cobalt as possible ingredients in his alloy, but iron remains the favorite. On alleging as true the substance of the foregoing the patentee sought and obtained the wide claim above quoted.

"Defendant has imported and sold a substance manufactured by Kunheim & Company, of Berlin, said to be composed (in accordance with specification of Huber, U. S. Patent 967,775, Aug. 16, 1910), of magnesium, 15 per cent, and cerium, 85 per cent, treated with hydrogen at between 500 deg. C. and 600 deg. C., as long as any absorption of hydrogen can be detected. The magnesium-cerium compound is pyrophoric, the alleged effect of absorbing hydrogen is to increase that quality.

"The defence asserts:

"(1) Welsbach's invention to be void for lack of novelty, i.e., it covers only a 'pre-existing inherent natural property of the alloy.'

"(2) Kunheim's product is not an alloy at all, and therefore not an infringement.

"(3) The claim in suit is (in view of the prior art) too narrow to cover any alloy not containing substantially the preferred quantity of iron—or possibly nickel or cobalt.

"*First:* This defence will not stand analysis. It is true that great pyrophoric activity is, and always must have been, an inherent natural quality in an alloy of iron and cerium. It is also true that any composition of matter has inherent natural qualities—but before such qualities can be known and used—the matter composition must be produced. Nature does not produce the alloy of Welsbach, and if that alloy is novel and artificial, the compound is patentable as far as novelty is concerned.

"*Second:* The dictionary meaning of alloy is 'an artificial compound of two or more metals combined while in a state of fusion.' The important words (for this case are, *two or more metals*, and all the experts examined agree that an alloy must contain that number.

"Admittedly both magnesium and cerium are metals, and the best and sufficient evidence that defendant's product was once (at all events) an alloy, is that Huber calls it one, and defendant insists that what Huber describes—it sells.

"But it is said that the hydrogen bath has created a *cerium hydride*, which is something so different from a mere alloy of cerium and magnesium as to be a different thing, i.e., a chemical compound of admittedly uncertain properties and formula.

"On such a point as this I am as far as possible from hazarding any opinion other than one as to the weight of evidence. I see no reason to doubt the facts testified to by Drs. Fattinger and Olsen, i.e., that they made an amalgam of the alleged infringing substance, and liberated the hydrogen, thereby demonstrating that the hydrogen was physically not chemically combined with the cerium and magnesium. It seems to me that what Huber called an alloy, so remained, even though saturated (so to speak) with hydrogen.

"*Third:* The substantial question in this case is that of infringement, and that depends on the range of equivalents, permissible to the patentee . . ."

The decision then takes up the requirements of a "pioneer patent."

"Whether any given invention is a 'wholly novel device' or one of 'such novelty and importance as to mark a distinct step in the progress of the art' always and principally depends on how much men knew before they learned what the patentee taught.

"Before the disclosures of Welsbach it is, I think, shown that men knew nothing of the certain and reliable preparation or manufacture of a pyrophoric alloy. They thought they knew that cerium was pyrophoric, whereas they had merely observed sparks given out by an impure metal, without connecting the impurities and sparks, as cause and effect.

"Before Welsbach there was and could be no *art*, in pyrophoric substances, because the basis of all art, certain knowledge, was lacking. This patentee taught how certainly and knowingly to produce that which had been observed indeed, but not understood. Such invention is indeed pioneer.

"The argument against the above conclusions rests upon several patents, and the disclosures of numerous scientific publications.

"One good reference or publication is worth more than a volume of poor ones, and I select the German patents to Escales, the article of Hillebrandt and Norton and Moissan's article in *Der Elektrische Ofen* as covering the whole defence."

These are briefly reviewed by the Court and it is said that "Moissan is much nearer the point in his opinion (*meiner Ansicht*) that it would be better to use (for fire-making apparatus) 'an alloy of iron with uranium,' but he never did it, and he did not tell anyone just what to do.

"Prophecy is often greater than invention, but it is not patentable.

"Believing then that this is a pioneer invention, can the doctrine of equivalents be invoked to read the claim in suit, an *alloy* of cerium with any other metal, provided that such alloy be pyrophoric?

"On this head the first inquiry is whether the patentee has tied his own hands, by limiting his claims. Groth vs. International &c. Co., 61 Fed. Rep., 284.

"Such is asserted to be the case here, for iron only is mentioned in the claim; but the inventor shows that the cerium is to be alloyed with iron or its equivalent (line 67), so that the final question is what are the equivalents of iron in a pioneer patent, when the specification shows that the invention is far wider than the use of iron only.

"As has been often said, where a valuable invention has been made it is the duty of the Court to uphold that which was really invented.

"What Welsbach invented was a metallic alloy having certain desirable qualities—he knew and said that iron was not the only (though it was the most desirable) component with cerium.

"If a metal other than iron be used, does the resultant embody Welsbach's invention? This is the root query.

"The question is one of fact, not law, and the innumerable cases on equivalents are merely statements of how the minds of sundry judges have worked when sitting as jurymen.

"To me it is obvious that the usefulness of an alloy, i.e., a fusion of metals, was Welsbach's plainly disclosed invention—without knowledge thereof Huber would not have known that it was useful to make an alloy of magnesium and cerium, therefore, he used and uses Welsbach's invention and is an infringer."

---

## The Brown Cyanide Patent Decision on Appeal

In our issue of October, 1913, page 541, reference was made to the Brown cyanide process patent decision, by which in the United States District Court for the District of Delaware (Judge Edward G. Bradford) the Tonopah Mining Company was found to have infringed a patent of Alden H. Brown. This decision has now been reversed by the United States Circuit Court of Appeals for the Third District (Judges Gray, Buffington and McPherson) and the case remanded with instructions to dismiss the bill for non-infringement.

Brown's patent has special reference to the sequence of several steps by which the metals are recovered by cyanidation and concentration. Customarily an ore requiring both concentration and cyanidation is subjected to the treatment in the order mentioned. Brown's patent covers the reverse method, viz., cyanidation followed by concentration. His second or broad claim reads: "A process of treating sulphide ore consisting first in subjecting the raw or unroasted ore to the action of a cyanide solution whereby the finer metallic values are dissolved, and second, subjecting the ore or tailings to concentration whereby the coarser values are recovered."

In the decision of the Court of Appeals, written by Judge Buffington, Brown's invention is analyzed at some length.

"It will be noted that no new principle of operation, either in cyaniding or concentrating themselves was disclosed in this patent. It was at most simply a more effective treatment and it will thus be seen that transposition of concentration from initial to final stage, and of cyaniding from final to initial stage is the substantial disclosure of this device. Assuming, for present purposes, that this change was original with Brown, and that it involved invention it must be conceded the field of invention was narrow, and Brown's claim should not by construction be enlarged to include within infringing fences processes which were not within the field of his inventive disclosure. Not without entering into details it suffices to say that the second claim embodies the two elements of, first, cyaniding, viz., 'subjecting the raw or unroasted ore to the action of a cyanide solution whereby the finer metallic values are dissolved,' and, second, concentrating, viz., 'subjecting the ore or tailings to concentration, whereby the coarser values are recovered.' This claim is perfectly clear. A reading of the patent shows precisely what the patentee disclosed, and the claim precisely claims that disclosure. There is no ambiguity in either disclosure or claim. They are self-sufficient and self-explanatory.

"This two-staged process, first, cyaniding; next, concentrating, being the only disclosure of Brown and the claims embodying these two separate, individual, completed stages or steps, it follows that any process which makes concentration an intermediate and completed step, one that precedes final and effective cyaniding, is a process different from the one Brown disclosed and claimed. Measuring the defendant's process by these standards, it follows that infringement is not shown, for, without entering into a detailed description of its plant, it suffices to say that a study of its workings has brought us to this conclusion. The defendants, in common with Brown, it may be conceded, are using the cyanide solution in the earlier stage of their process, and to that extent we may say initially utilize the general chemical treatment incident to cyaniding, preparatory to concentrating. But beyond this the resemblance ceases, for by defendant's process concentration—effective, finished and final—is the initial and intermediate step in their process. At such intermediate step the fruits of concentration are withdrawn from the process, and this first completed step of the process, the one 'whereby the coarser values are removed,' is, as we have seen, the second step of Brown's process.

"After the defendant's concentration is finished, the by-product goes forward to be subsequently treated by a protracted process of cyaniding. This is at variance with Brown's process in three respects, first, cyaniding follows concentrating; second, it is a system condemned by Brown and one he sought to avoid in that where 'concentration . . . is used preliminary to the cyanide process it will be necessary to have a very extensive system of settling tanks in order to recover these suspended values and hold them in the mill so that they may be subjected to further treatment'; third, the defendant's process which physically withdraws from the operation of the process the products of concentration in advance of withdrawing those of cyaniding, makes the process one avoided by Brown, viz.: 'It is a well-known fact that the cyanide process recovers only the fine values and in the treatment that I have devised these fine values are recovered by the cyanide process in the beginning, leaving only the coarser values, which are readily recoverable by concentrating, the latter being specially adapted for saving this class of values.'

"It is apparent, therefore, that the defendant's device, which the proofs show has been of great practical worth, owes its worth to the fact that it is built and operated in express disregard to the instructions of Brown's patent. Without passing on the question of the validity of that patent it suffices to hold defendants do not infringe."

BUST OF MORRIS LOEB

## Presentation of the Bronze Bust of the Late Morris Loeb to the Chemists Club

At a meeting of the New York Section of the American Chemical Society, held in the Chemists' Building, New York City, on March 6, 1914, a bronze bust of the late Morris Loeb was dedicated and presented to the Chemists Club.

Dr. L. H. Baekeland, in his speech of presentation, sketched the ideals of Morris Loeb and his work for chemistry in America and the Chemists' Club. Dr. Baekeland concluded as follows:

"After his untimely death, which left so many in sorrow, it was found that by his will Morris Loeb had planned the realization of the ideals he had preached.

"To his university, Harvard, he left a large sum of money for chemical research; to the Chemists' Building, he gave all his shares; to the American Chemical Society, he left a fund for the creation of a chemical museum along the lines conceived and clearly described by him.

"None of us, who have known Morris Loeb, who have lived, worked, or spoken with him, need a bust nor a portrait to remind us of the man or his work. But as we grow older and death keeps thinning out our ranks, younger generations of chemists will use these halls. Our duties, our responsibilities will become their duties, their responsibilities.

"I have no doubt that their aims for good will be of the highest; that they will better realize than the present generation that to be a chemist is to be an apostle of progress and civilization, of justice and truth.

"But the chemists of the coming generation will not have known Morris Loeb, and we must remind them of what one of our generation dreamt, planned and did for them.

"This is the reason why some friends of Dr. Loeb obtained a bronze bust from Mr. Karl Bitter, an artist whose reputation is no longer to be made.

"It is their desire that this bust should adorn the halls of the Chemists Club.

"Dr. McKenna, upon you, as president of the Chemists Club, devolves the responsibility of placing this bust where it will best serve its purpose."

---

**The preliminary report on mineral production in Canada in 1913**, by the Dept. of Mines, shows a total value of production in the year just closed of $144,031,047. Although estimates have been made in some cases where complete returns were not available, it is probable that the final record will be a revision upward. The total value of the production in 1912 was $135,048,296, compared with which the 1913 output shows an increase of $8,982,751, or 6.65 per cent. In view of the large increase over all previous years made in mineral production in 1912 and the general trade depression and industrial restriction experienced during the latter part of 1913 the industry would appear to have made in the aggregate very satisfactory progress. The average production per capita in 1913 was $18.57, as against $18.27 in 1912 and $14.93 in 1910.

## Program of New York Meeting of American Electrochemical Society

The twenty-fifth general meeting of the American Electrochemical Society will be held in New York City on Thursday, Friday, and Saturday, April 16 to 18.

The headquarters will be at the Chemists' Club, 52 East Forty-first Street. There will be technical sessions on the morning and afternoon of Thursday in Rumford Hall in the Chemists' Building, 50 East Forty-first Street, and on Saturday morning and afternoon in Earl Hall, Columbia University. There will be a smoker on the evening of Thursday in Rumford Hall, Chemists' Building, and a dinner-dance on Saturday evening also in the Chemists' Building.

On Friday there will be an all-day excursion by steamboat around New York Harbor and Staten Island combined with visits to the plants of the American Smelting & Refining Company, the United Lead Company, and the Waclark Wire Company. The arrengements for the meeting are in the hands of the New York Section of the American Electrochemical Society, and the smoker on Thursday night and the steamer party on Friday are complimentary affairs tendered by the New York Section.

The program of the technical sessions is as follows:

**Thursday, April 16, 9 a. m.,** Rumford Hall, Chemists' Building: Annual business meeting, followed by Symposium on Power Problems in Electrochemistry:

C. P. Steinmetz, Characteristics of Electrical Energy as Affecting Chemical Industries.

P. Sothman, Efficiency of Power Transmission Versus Utilization in Local Electrochemical Industries.

F. A. J. FitzGerald, Economics of Electric Furnace Operation.

W. S. Horry, Power Supply to Electric Furnaces.

Lawrence Addicks, The Power Problem in the Electrolytic Deposition of Metals.

H. E. Longwell, The Power Problem in the Electrolytic Deposition of Metals.

F. D. Newbury, Sources of Direct Current for Electrochemical Processes.

General discussion.

**Thursday, 2 p. m.,** Rumford Hall, Chemists' Building:

Wilder D. Bancroft, Electrolytic Flames (An Experimental Lecture).

C. A. Hansen, Electric Steel Castings.

Eugene B. Clark, Electric Furnaces for Steel Making.

G. C. Stone, Improvements in the Metallurgy of Zinc.

W. R. Ingalls, Electric Zinc Smelting.

W. P. Lass, Advantage of Southeastern Alaska for Hydro-electrochemical Industries.

**Thursday, 8 p. m.,** Rumford Hall, Chemists' Building:

E. F. Roeber, Some Economic and Aesthetic Aspects of Electrochemistry (Presidential Address).

**Thursday, 8.45 p. m.,** Smoker.

**Saturday, 9 a. m.,** Earl Hall, Columbia University:

E. A. C. Smith, Progress in Leaching and Electrolytic Treatment of Copper Ores in South America (A Lecture).

R. R. Goodrich, Hydro-electrometallurgy of Copper.

Rudolph Gahl, Leaching of Copper Tailings.

Ralph W. Deacon, Metal Inventory in an Electrolytic Copper Refinery.

Joseph W. Richards, Electrolytic Zinc.

O. P. Watts and A. C. Shape, Addition Agents in the Deposition of Zinc from a Solution of Zinc Sulphate.

Frank C. Mathers and O. Ralph Overman, The Effect of Addition Substances in Lead Plating Baths.

Frank C. Mathers and Hugh M. Marble, Electrodeposition of Cadmium.

C. W. Bennett, H. C. Kenny and R. P. Dugliss, Electrodeposition of Nickel.

C. W. Bennett and A. W. Davison, Electrolytic Deposition of Brass on a Rotating Cathode.

Gustave E. F. Lundell, A New Method for the Determination of Free Cyanide in Electroplating Solutions.

**Saturday, 2 p. m.,** Earl Hall, Columbia University:

E. F. Northrup, Electric Conduction at High Temperatures and Methods of Measurement (An Experimental Lecture).

F. A. J. FitzGerald, Laboratory Notes on Some Electrical Properties of Silver Sulphide (with experiments).

Claude N. Hitchcock, Polarization Single Potentials.

Reinhard Beutner, New Cell Arrangements for Direct Determination of the Free Energy.

R. Stuart Owens, Experiments on White Lead.

Oliver W. Storey, A Microscopic Study of Electrolytic Iron.

O. P. Watts and M. H. Li, The Effect of Addition Agents in the Electrodeposition of Iron.

O. L. Kowalke, Base-Metal Thermocouples and Their Microstructure.

**Saturday, 7 p. m.,** Subscription Dinner, followed by Dancing, at the Chemists' Club.

The arrangements of the meeting are in the hands of the New York Section, of which Mr. Lawrence Addicks is the chairman and Mr. H. B. Coho (United Lead Company, 111 Broadway, New York City) is the secretary.

## The Western Metallurgical Field

### Flotation and Cyaniding

Flotation processes have been used mainly with the object of producing from ores a marketable concentrate for subsequent smelting. Low-grade zinc and copper ores are thus treated quite extensively. Another possible field for flotation, which has not received very much attention, is the concentration of gold ores, with the idea of cyaniding the concentrates thus produced. Some preliminary work along this line has been done by Mr. Justin H. Haynes, and the proposal seems worthy of consideration in cases to which it is applicable. The type of ore most amenable to such a process would be a simple pyrite in silicious gangue, the gold and silver being contained wholly or mainly in the pyrite and not distributed through the gangue. From this ideal condition we might extend the process to ores containing some galena also; but the principal point to be observed would be the association of the precious metals with the sulphide constituent, so that on floating the concentrate the tailing might be discarded as worthless.

The rejection of sand tailing characterizes some present operations in which table concentration plays a part. Thus at Cripple Creek, the Portland company first concentrates the ore, removing sulpho-tellurides, and then classifies the remaining pulp into sand and slime, discarding the former. A similar procedure was in effect at Idaho Springs when the Hudson mill was running. Of course, there are districts in which the nature of the ore will not permit the rejection of the sand.

Flotation, however, might offer some advantages even in the cases cited, for it would recover in one concentrate the slime mineral as well as the coarse which is now caught on tables, and thus render the slimy as well as the coarse gangue without value. We would then have for treatment by cyanidation only the concentrate, which would be but a fractional part of the crude ore. The cyanidation of concentrates is practiced in numerous places. Where this is possible, flotation would be an excellent means of first getting *all* the mineral in a concentrate of high grade. The cost of cyaniding and the metallurgical losses sustained in that process would then be greatly reduced when calculated per ton of crude ore, and certain refinements could be introduced that would be prohibitive if applied to original ore. The object of flotation would not be the production of a marketable concentrate, containing as little gangue and as much mineral as possible, but primarily to get all the mineral, even though it was accompanied by more gangue than would be permissible if the concentrate were to be smelted. The cost of the cyaniding plant would be greatly reduced, as also would that of the concentrating department, and a mill based on such a process might come within the means of companies owning small mines.

### Smelters and Farmers

Rumor has been current to the effect that the farmers of the Tooele district in Utah expect to make trouble for the International Smelting & Refining Co., which has a large copper and lead smelter there. It is unlikely that such will be the case, or at least it seems so in view of the elaborate precautions taken by the company before the smelter was located there and before operations were commenced. At that time the company had experts in the field making observations on the condition of the flora of the region, with special reference to agricultural and horticultural crops. It is understood that the company at that time took options on much of the land, with the intention of buying them if the farmers preferred to sell. Under these conditions it seems doubtful if the farmers could present a good case, and it is likely that many of them will care less about litigation when they find that the company stands ready to buy their land.

The situation in California is not so favorable to the smelters, and some interesting developments may occur there this summer. Incidentally it may be stated that experimental work with the Hall process of distilling and recovering sulphur from ores is proceeding, and that the early results are encouraging.

### Chlorination Processes in Utah

Mention has been made previously in this column concerning the adoption of a process of chlorination at two mills in Utah: one at Park City, where the Mines Operating Co. is treating ore from the old Ontario; and the other at Silver City, where Jesse Knight is completing a new mill. Within the past month it has been announced that a third mill, also at Park City, is to adopt a similar process. The dry concentration mill formerly operated there by the Grasselli Chemical Co., treating zinc middlings, has been purchased by Salt Lake parties, and will be remodeled into a custom mill using a process based on chloridizing-roasting and leaching. Ore from the American Flag mine, among others, will be treated. The owners of this property have been making metallurgical investigations for some time, seeking the best method of recovering gold, silver, copper, lead and zinc, all of which exist in the ore in small quantities. We are informed that concentration has yielded poor results. A combination of concentration and cyaniding has done much better, but the process which has been adopted is said to have yielded by far the best results, with a probability of making a good recovery of all the valuable metals. The anticipated cost of treatment is given as $3.50 per ton, and the recovery as over 90 per cent of all the metals.

### Oil Flotation at Butte & Superior

According to a report filed by the Butte & Superior Copper Co. in the federal court, in accordance with the court's order pending settlement of a suit brought by the Minerals Separation, Ltd., the company treated in January by flotation 29,188.9 tons of ore, yielding 7062.6 tons of concentrates. The cost of this part of mill operations is given as $4.225 per ton, and the value of concentrate as $23.45 per ton. About 88 per cent of the ore handled in the mill was treated by flotation. The following tabulation shows the results of flotation on that part of the tonnage thus treated.

| | Heads | Concentrates | Tailings |
|---|---|---|---|
| Zinc, per cent | 13.91 | 50.71 | 2.06 |
| Lead, per cent | 0.77 | 4.43 | 0.15 |
| Copper, per cent | 0.19 | 0.45 | 0.04 |
| Iron, per cent | 2.73 | 1.39 | 0.94 |
| Manganese, per cent | 1.44 | 2.72 | 0.85 |
| Insoluble, per cent | 68.87 | 10.82 | 91.50 |
| Silver, oz. per ton | 7.73 | 26.55 | 1.62 |
| Gold, oz. per ton | 0.02 | 0.05 | 0.004 |

### Company Reports

*The Arizona Copper Company, Ltd.*, has made public a report of its operations for the year ended September 30, 1913. The year's production of copper was 34,230,000 lb., being less by 3,920,000 lb. than for the preceding year. This decrease is partly accounted for by a lower grade of ore and by delay in getting the new smelting works in operation up to capacity. The ore mined from the company's properties yielded 38.76 lb. copper per ton, a decrease of 2.39 lb. per ton as compared with last year. During the year 780,887 dry tons of ore was concentrated, 68.7 per cent of the quantity being handled at No. 6 concentrator and the balance at the Clifton concentrator. The average ratio of concentration was 7.26 to 1. The work at No. 6 has been handicapped by reconstruction which has been under way. Hardinge mills have been substituted for Huntington mills. The works for treating oxidized ore by concentration handled 106,596 dry tons of ore, and 85,071 tons of tailings from this concentrator was leached. The copper recovered from oxidized ores amounted to 9.27 per cent of the total production. In the smelting department a total of 151,265 tons of ore and concentrates was smelted. The average yield of copper from material smelted was 11.31 per cent. The old smelting plant was closed on December 31, 1913, the new plant having been started in August.

From the report of the *Mount Morgan Gold Mining Co., Ltd.*, Mount Morgan, Queensland, we excerpt the following items on operation as given by Mr. B. Magnus, general manager. The following table gives statistics from the reduction works for the six months ending November 30, 1913:

| | Tons | Copper obtained, tons | Copper, per cent | Gold, ozs. obtained | Gold, dwts per ton |
|---|---|---|---|---|---|
| Copper ore | 123,247.00 | 3,852.49 | 3.125 | 52,484.58 | 8.516 |
| Many Peaks ore | 25,632.00 | 336.63 | 1.313 | 198.26 | .154 |
| Purchased ores | 45.77 | 7.75 | 16.932 | 60.80 | 26.567 |
| Miscellaneous products | 3,091.19 | 157.19 | 5.085 | 2,248.86 | 14.550 |
| | 152,015.96 | 4,354.06 | 2.864 | 54,992.50 | 7.235 |

The copper ore smelted assayed about 55.6 per cent silica, which is 3 per cent higher than for any previous period. This has entailed extra expense for fluxing material, and has added to cost of operation, as it costs approximately 6½d. (13c) per unit to flux silica. This points to the necessity of getting the concentrator in operation as soon as possible. When the latter is running, ore containing over 52 per cent silica will not be smelted direct unless it is high in gold content. Experimental work in concentrating has proceeded, and a representative of Minerals Separation has been on the ground to check up the work. The recovery is better than estimated, and the cost is less. Serious delay has been experienced in delivery of steel for the new smelter building, and has materially deferred the blowing in of the new plant. A Dwight-Lloyd sintering plant will be installed to handle flue dust.

## "Skin Effect" in Carbon Electrodes

BY A. T. HINCKLEY

At the spring meeting of the American Electrochemical Society in 1912, Mr. Turnbull's paper on Furnace Electrodes gave rise to some discussion as to the magnitude of the "skin effect" in large electrodes. No one apparently had any figures on the subject, and the question was settled by the opinion of Mr. Hansen that the effect should not be large owing to the relatively high resistivity of carbon.

Since that time the question has come up several times whether or not carbons in the form of hollow cylinders would give longer life in electric furnace work, as the "skin effect" would be less in such carbons than in the solid cylindrical ones. As far as we know there have been no figures published concerning this up to the present time.

In the *Journal* of the Franklin Institute for February, 1914, Mr. Carson, working with Dr. Northrup at Princeton University, has given a mathematical treatment of the "Skin Effect and Alternating-Current Resistance" phenomena. From these data we have calculated the magnitude of this effect in 24-in. round carbon electrodes.

$R_{ac}$ = resistance per unit length for alternating currents.

$R_{dc}$ = resistance per unit length for direct currents.

The magnitude of the ratio $\frac{R_{ac}}{R_{dc}}$ is desired.

$$\frac{R_{ac}}{R_{dc}} = \frac{1 + c_1\left(\frac{\mu f a^2}{\rho}\right)^2 + c_2\left(\frac{\mu f a^2}{\rho}\right)^4 + \cdots}{1 + \frac{c_1}{2}\left(\frac{\mu f a^2}{\rho}\right)^2 + \frac{c_2}{3}\left(\frac{\mu f a^2}{\rho}\right)^4 + \cdots}$$

$c_1 = 6.49 \times 10^{-5}$

$c_2 = 3.55 \times 10^{-10}$

$\mu$ = permeability

$f$ = frequency in cycles per second

$a$ = radius of conductor in cm.

$\rho$ = specific resistance per cm cube, in microhms.

For a 24-in. round carbon electrode used on a twenty-five-cycle circuit,

$\mu = 1$ (practically)

$f = 25$

$a = 30.48$

$$\rho = \frac{0.0020 \times 6.45 \times 10^6}{2.54} = 5100$$

$$\frac{\mu f a^2}{\rho} = \frac{1 \times 25 \times 30.48^2}{5100} = 4.54$$

$$\frac{R_{ac}}{R_{dc}} = \frac{1 + 6.49 \times 10^{-5}\,(4.54)^2 + \ .\ \ .}{1 + 3.24 \times 10^{-5}\,(4.54)^2 + \ .\ \ .}$$

$$= \frac{1 + 133 \times 10^{-5}}{1 + 67 \times 10^{-5}}$$

$$= \frac{1.00133}{1.00067}$$

That is, the $R_{ac}$ of a carbon electrode 24 in. diameter is only 0.066 per cent higher than the $R_{dc}$. On this account there would be practically no tendency for the alternating current to concentrate at the surface of the carbon and the use of a hollow cylindrical carbon in place of a solid one becomes unnecessary.

Research Laboratory, National Carbon Co.,
Niagara Falls, N. Y.

**The annual trip of inspection** of the senior class of the Colorado School of Mines will start from Denver on April 20 and last four weeks. The principal mining and metallurgical centers of Colorado, Utah and Montana will be visited.

## The Electric Iron Ore Smelting at Hardanger in Norway—II.

BY JOH. HÄRDÉN

In an article* in the February issue, page 82, I gave an account of the first part of Mr. G. Oedqvist's paper, read before the Polytechnic Society of Christiania.

In the following, the second part of Mr. Oedqvist's paper, published in *Teknisk Tidskrift*, Jan. 28, 1914, will be reviewed.

### The Quality of the Pig Iron

The results at Hardanger have shown that it was quite possible to produce a good quality of pig iron, free from obnoxious impurities, although coke was used as reducing agent. But the uniformity of the product was far from satisfactory.

The principal reason of the considerable variations in the product is to be found in the undesirable fluctuations of the power consumed by the furnace, with which the author deals further on, and which caused great variation of the temperature in the smelting zone. The real reason of the poor uniformity of the product is therefore, according to Mr. Oedqvist, to be found in the furnace itself.

These variations will be even more prominent when coke is used solely, instead of charcoal .

However, such great variations as those at Hardanger need not always occur, as is evident from the results during the last period when a considerable improvement was obtained. It is clear that the faulty electrical arrangement has had a great influence in this respect as well as with respect to the large percentage of scrap produced.

### Stoppages and Interruptions

Table VI shows the stoppages at Hardanger, compared with Uddeholm and Strömsnäs.

TABLE VI

| | Stoppages in Per Cent | Interruptions per 24 Hours in Average, Hours |
|---|---|---|
| | About | About |
| Hardanger, Period I | 20.8 | 5 |
| Hardanger, Period II | 8.5 | 2 |
| Hardanger, Period III | 3.0 | ¾ |
| Hardanger, Period IV | 14.0 | 3 1-3 |
| Uddeholm, Furnace No. 1, March 15 to December 31, 1912. | 4.0 | 1 |
| Uddeholm, Furnace No. 2, August 1 to December 31, 1912 | 4.2 | 1 |
| Stromsnas, October 1 to December 31, 1912 | 2.2 | ¼ |

Standstills at Trollhättan during the period from Aug. 4, 1911, to Sept. 30, 1912, amounted to about 5.5 per cent. One of these stoppages not due to the working of the furnace or directly caused thereby amounted to 4.7 per cent, while only 0.8 per cent interruptions were directly due to the furnace, corresponding to about ten minutes for each day of twenty-four hours.

The individual causes for the stoppages at Hardanger are not stated in the reports issued, but it appears most likely that the numerous interruptions were mostly caused by breakage of electrodes. That these interruptions had a decisive effect on the uniformity of the product and the general results is quite certain and need not be further explained.

---

*In this article there is an error on page 83. Line 13 and the following lines of the first column should read: "Hence it seems very likely that a regulation of from 45 to 75 or 80 volts would have been sufficient, with a booster for raising the voltage to say 90 or 95 volts, to be resorted to in cases of emergency, to break through the charge if this furnace got cool after a tapping."

### The Load Factor

Table VII shows the electrical load of the furnace at Hardanger, taken as an average for the two best periods.

TABLE VII

| The Hardanger Furnace for the Period | Normal Average Load in K.W. | Average Minimum Load | | Average Maximum Load | |
|---|---|---|---|---|---|
| | | In K.W. | Decrease in Per Cent of Average Normal Load | In K.W. | Increase in Per Cent of Average Normal Load |
| | | | About | | About |
| September 7 to September 21, 1912. | 1736 | 804 | 54 | 2207 | 27 |
| March 6 to March 29, 1913 ... | 2004 | 756 | 62 | 2857 | 42.5 |

The table shows that the variations in power consumed by the furnace were very great, and that an overload capacity of at least 42.5 per cent above the average normal load was required.

The author does not state the duration of these variations in detail, although especially the period of the overload is of importance in its bearing upon the size of the power plant.

The paper concludes: These irregularities, which were prevailing at the furnace and which were caused by the variations in resistance to which the descending mass of charge was subjected, prevented largely an economic utilization of the available power supply.

The same disadvantages are also well known from some other furnaces in which electrodes are used. The experiences at Trollhättan show that about 200 kw above the normal load must be provided for.

Practically all furnace plants require such overload facilities, at least to a certain extent, since some variations are almost inevitable at times.

At Hardanger, where coke was used only, the above figure of 200 kw was not sufficient, since at least 850 kw over the normal load was occasionally required, and at times even as much as 1000 kw.

This seems to indicate that the use of coke is a direct reason for these variations, especially when the volume of the charge is large in comparison with the volume of the coke.

The paper quotes an extract in this connection from statements made at Trollhättan, from "The Jernkontorets Annaler," 1912, page 319:

"Now it is to be noted that the resistance of the charge in the smelting zone varies for one and the same kind of charge, according to the depth of the iron bath, and in addition, considerably for various kinds of charges. A rich charge, with a small addition of lime only, will cause a rise of the current, and this increase in current consumption will be greater as the 'charge setting' is less, or, in other words, the greater the proportion is between the volumes of the charcoal and the ore charges. A less rich charge again (which also frequently calls for a higher percentage of lime) is acting in the opposite direction, so that a higher voltage is required to obtain the same current density as in the first case."

"We have had sufficient experience in this respect and if the last-mentioned conditions were prevalent, the voltage of 90 volts, which was our maximum voltage obtainable without reconnecting the transformers, was even not quite sufficient during the first hour after tapping, so that the power decreased several hundred kilowatts."

At Hardanger, where no booster was provided and the maximum voltage was only 78 instead of 90 volts as at Trollhättan, the discrepancies must have been even greater, since coke was used.

(This seems not quite evident to our mind, since a coke charge as a rule has a lower resistance than a charcoal charge, although the volume of the coke is less than that of the latter; an increase of the voltage would have heated up the current path in a comparatively short time, to permit a subsequent decrease to the normal.)

The paper continues: As the low voltage range could not be altered without considerable cost, it seems that the best remedy would have been to work with a richer charge. Instead of this, however, the works at Hardanger chose the opposite way. They abandoned the richer charges and commenced to use Persberg ore with 53 per cent Fe and a charge, giving only about 42 per cent yield.

The result was that the variations in load became greater during this period, compared with the foregoing one, when the charge was richer.

### Production

The output of pig iron per year is, of course, of the greatest importance, as far as the economic result generally goes. Table VIII gives a fair idea of the output compared with the results from Trollhättan, Uddeholm and Strömsnäs.

TABLE VIII

| Plant | Per Cent Pig Iron of Goods | Production | | Average Load in Kilowatts | H.P. Available for the Furnace | Tons Pig Iron | | | Yearly Production in Tons | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Tons per 24 Hours | Tons per 24 Hours, Actual Work | | | Calculated H.P. Year | Per Actual H.P. Year | | Calculated | Real[1] | |
| | | | | | | | At 365 Work Days | At 335 Work Days | | Per 365 Work Days | Per 335 Work Days |
| Hardanger, Period I ... | 38.1 | 5.95 | 7.51 | 1665 | 3500 | 1.28 | 0.62 | 0.57 | 2743 | 2172 | 1993 |
| Hardanger, Period II | 50.7 | 9.6 | 10.55 | 1734 | 3500 | 1.58 | 1.0 | 0.92 | 3850 | 3505 | 3217 |
| Hardanger, Period III | 56.4 | 12.11 | 12.48 | 1703 | 3500 | 2.01 | 1.26 | 1.16 | 4555 | 4419 | 4056 |
| Hardanger, Period IV | 41.65 | 10.48 | 12.16 | 1942 | 3500 | 1.87 | 1.09 | 1.0 | 4447 | 3827 | 3512 |
| Trollhattan, Aug. 4, 1911 to March 6, 1912 | 56.84 | 14.92 | 15.98 | 1482 | 2850 | 2.9 | 1.56 | 1.43 | 5834 | 5445 | 4997 |
| Trollhattan, Aug. 12, 1911, to September 30, 1912 | 63.77 | 19.53 | 19.72 | 1653 | 2850 | 3.2 | 2.5 | 2.3 | 7213 | 7128 | 6542 |
| Uddeholm, No. 1 | 53.5 | 16.82 | 17.52 | 1940 | 3235 | 2.45 | 1.9 | 1.74 | 6395 | 6141 | 5636 |
| Uddeholm, No. 2 | 52.9 | 19.31 | 20.15 | 1998 | 3235 | 2.7 | 2.18 | 2.0 | 7355 | 7046 | 6467 |
| Stromsnas .. | 61.78 | 20.72 | 21.2 | 1833 | 2850 | 3.1 | 2.65 | 2.45 | 7736 | 7561 | 6940 |

The column "Tons of pig iron per calculated hp-year" refers to the amount of iron, which would have resulted per hp-year, if the power is taken only as per average load, without any stoppages, for a period of fully twelve months. Tons of iron per actual or real hp-year again means the actual quantity produced in proportion to the amount of power provided for the furnace with a smelting time of 365 and 335 days per year, or 12, respectively eleven months.

The "calculated" yearly production refers to the output which would result during twelve months, without interruptions, and the "real" production indicates the output resulting when stoppages are considered and the smelting period is both twelve and eleven months.

The total production per year at Hardanger was, as the table shows, considerably less than from the other plants, in spite of the fact that the Hardanger plant had the largest electrical equipment.

The causes of such a low production figure is, according to Mr. Oedqvist, that only a small proportion of the power available could be utilized in the furnace, as compared with the other plants, and that this was to a great extent the direct result of the attempt to use coke as reducing agent. Further, that the charge as a general rule had too low percentage of iron. The insufficient electrical arrangements also largely influenced the results during the three first periods.

The above statement by the author of the paper seem to utterly condemn the use of coke for this industry. While this may be so for the plant in question, it would be, to our mind, premature to claim this as a general rule. Trials have shown that coke can be used with good results, if the conditions otherwise are suited for that material, though charcoal would be the ideal reducer. But as already said, this material is gradually rising in price to such an extent that its use is very limited; hence it seems inevitable that serious steps are called for, to enable the use of the more common coke, even if the power-consumption per ton of iron should be thereby increased.

### The Electric Efficiency

The electric energy required for this metallurgical process, as compared with the amount of power provided for the plant, is called "the real electric efficiency" by the author of the paper.

This does not include such power as is required for auxiliary machinery necessary, etc., but such losses as occur in the transformers, the power line, cooling of contacts (holders, etc.), radiation losses, variation in working, etc., are included.

Some of the data, which have a bearing upon this, are lacking, wherefore the following figures are more or less approximate, but as they are of general interest they are reproduced in the paper.

TABLE IX

| Plant | The "Real" Electric Efficiency, Per Cent |
|---|---|
| | About |
| Hardanger, Period I | 23 |
| Hardanger, Period II | 30 |
| Hardanger, Period III | 30 |
| Hardanger, Period IV | 41 |
| Uddeholm, Furnace 2, August 4 to December 31, 1912 | 57 |
| Strömsnäs, October 1 to December 31, 1912. | 60 |

The above figures should not be regarded as an absolute statement of the efficiency of the respective furnaces, but show the working efficiency only under the specific conditions prevailing during the periods mentioned.

### Cost of Electric Energy Per Ton of Pig Iron

The comparative costs of electric power per ton of pig iron produced, both at Hardanger, Uddeholm and Strömsnäs, are shown in Table X.

TABLE X

| | COST OF ELECTRIC POWER | |
|---|---|---|
| | Per Calculated Ton of Pig Iron, Shillings | Per Actually Produced Ton of Iron, Shillings |
| Hardanger, Period I | 42.53 | 58.52 |
| Hardanger, Period II | 30.30 | 36.265 |
| Hardanger, Period III | 25.61 | 28.77 |
| Hardanger, Period IV | 26.23 | 33.21 |
| Uddeholm, Furnace I | 16.86 | 19.13 |
| Uddeholm, Furnace II | 14.66 | 16.66 |
| Strömsnäs | 12.28 | 13.69 |

The figures for "per calculated ton of iron" refer to the cost per ton as calculated for an output which would have resulted if no stoppages had taken place. The other column, marked "per actually produced tons of iron," includes all stoppages. The table is drawn up under the assumption that the furnaces could be working fully eleven months per year.

The initial cost of power is taken to be equal for all three plants and assumes to be 33.33 shillings per hp-year.

Luton, England.

## Some Notes on Stamp-Mills and Milling

BY WM. H. STORMS

There has already been published a large amount of literature on the stamp-mill, so the subject is by no means a new one, but in the following I wish to call attention to a number of matters connected with stamp-mills and milling that usually receive little consideration from those who write on the subject, probably because these matters, in themselves, are so simple that they seem to deserve no particular mention.

I believe, however, that there are many who will find something herein that will be useful to him if he is called upon to run a stamp-mill.

### Something About Mortar-Blocks

There has come to exist a very general belief that the mortar of a quartz-mill must have solid bedrock as a base for the mortar-block, and that without it disaster is sure soon to follow. It is desirable to have a bedrock foundation if it can be easily obtained, but it is by no means imperative that the mortar-block, whether of wood or of concrete, rest upon bedrock.

If the block be of wood and a bedrock foundation is readily accessible, it is good practice to lay a foundation of concrete at least 14 in. thick (18 in. is better), in the bottom of the pit on the bedrock, for the reason that the bedrock surface exposed may be of unequal hardness, and should this prove to be the case, the mortar-block is likely to discover the fact later and a movement begun in the wooden structure which will, in time, cause the mortar to have a rocking motion, which is about as undesirable a thing as could happen.

Such a motion is most undesirable for various reasons. It causes the vibrations of the mortar to be unequally distributed; anchor bolts are likely to break, and other damage result, which might have been avoided had a concrete bed been first properly laid. If a bedrock base is unobtainable at reasonable depth, 16 to 18 ft., at most, then the entire mortar block should be made of concrete, giving the sides and ends such a slope angle as will insure a broad base.

Cut the bottom of the pit as nearly level as possible and then build the form within which the concrete is to be placed.

The concrete should be made of clean rock, sharp, clean sand and the best quality of cement obtainable, for the block is to be subjected to what is, perhaps, the hardest usage that concrete foundations are ever required to withstand. A good concrete mixture consists of four parts of clean firm rock, broken to pass a 2½-in. ring; two parts of sand and one part of dry cement. The concrete should be dumped into the form as fast as mixed and rammed until water stands at the surface. When the concrete block is approaching the desired height it will be well to make the last 5 or 6 in. of a somewhat richer mixture, as this is less likely to crack.

If the mortar-block is to be of wood, have it at least 12 ft. long, and build it up by spiking 2 by 12-in.

planks together up to the desired dimensions, placing the planks parallel with the face or front of the mortar (not parallel with the ends). This will give an opportunity to make repairs to the block, or to renew any anchor bolts that may ever require it. Experience has shown that repairs of this kind are not easily made if the planks of the block be set parallel with the ends of the mortar.

Some engineers advise filling in the pit with concrete around the mortar-block. This will, of course, insure stability, but it also insures against making any repairs to the mortar-block without going to the expense of shooting out the concrete and thus exposing the wooden block.

In my opinion, the best way is to dig the pit at least 30 in. wider, on both front and back, than the space required for the block, which will give the necessary room for workmen when making repairs in future years. The pit need be but little longer than the length of the block itself.

In case a wooden block is to be set on a foundation of concrete 16 or 18 in. in thickness, it is best to first lay about 12 in. of concrete and on this place a mixture of sand and cement—3 parts sand to 1 part cement, which makes a very firm and enduring monolithic base.

Carefully chamfer the base of the wooden mortar-block on all sides, cutting away about 1 in. at the bottom, and gradually sloping it to the edge 4 in. above the bottom. Make a form of light boards (1 in. by 4 in.), battered so that they will be just the size of the chamfered lower edge of the mortar-block.

When the concrete and sand foundation has been laid as above suggested, place the wooden form in the position that is to be occupied by the mortar-block, and wedge it firmly in proper place. Then fill the space outside the frame with a grouting of cement-mortar, bringing it even with the top of the form. Allow this grouting to set, after which the form may be removed, leaving a depression on the top of the concrete block. Cover the bottom of the depression thus made with clean sand to the depth of 1 in., and the foundation will then be ready for the lowering of the mortar-block. This should be done by means of chain-blocks, the mortar-block so suspended that its top is level, and it is very necessary that when the block has reached the bottom of the pit that it enter exactly the depression made for it on the top of the concrete base. Every care must be taken to prevent loose rocks, dirt, or other foreign substance from falling into the pit before the mortar-block is lowered into position.

Some mill builders set up the battery frame before lowering the mortar-block into the pit, and without doubt, this is an excellent way, and dispenses with the necessity of a derrick or gin-pole. They build the mortar-block and finish it on the surface, anchor-bolt pockets, the chamfered edge at the bottom, and they even sometimes surface the top. The block, when completed, is moved into position exactly opposite the pit which is to receive it, the pit having first been covered with planks to prevent anything falling into it. The block is then raised by means of jacks, or otherwise, to an angle of about 45 deg., after which it is pulled into vertical position by means of block and tackle, the base resting upon heavy timbers placed across the pit to hold it. A 12 by 12 timber is then laid on top of the battery-posts and chain-blocks made fast beneath it, to lift the mortar-block clear of the timbers upon which it rests, and to control its descent into the pit when all is in readiness. The line-sills are then drawn up tightly, clamping the mortar-block firmly into exact alignment. The timbers and planks beneath the suspended block are carefully removed from over the pit, and when sure that nothing has fallen into the pit that would prevent the mortar-block from setting squarely on the base prepared for it, the block is allowed to slide downward, by easing up on the line-sills and operating the chain-blocks. When the block, at last rests on the concrete foundation the task is completed. The space around the block should be solidly filled with sand and water poured in to make the sand settle solidly. If tailings direct from a mill in the vicinity can be sluiced in so much the better.

### Battery-Post Construction

In this it is merely desired to call attention to the advantages of the four-post frame for units of 10 stamps, over three-post construction, though the latter are by far the more common. In the three-post frame the bull-wheel is at one end of the camshaft, and no matter in what direction the power is applied by the belt, there is a tendency to lift the camshaft out of the box at the opposite end from the bull-wheel, the bearing nearer the wheel acting as a fulcrum. The effect of this is to cause the cam-shaft to vibrate unnecessarily; to loosen the cam-shaft boxes; break up the babbitt-metal and eventually to twist the cam-shaft in two. True, this latter may never happen, particularly if the shaft be of liberal dimensions, but the tendency is in that direction, nevertheless.

If the 10-stamp battery be constructed with four posts, having the bull-wheel keyed between the two center ones, the pull of the belt is equalized as nearly as it can be and the vibrations of the cam-shaft are reduced to a minimum. I have never heard of a broken cam-shaft in a mill built in this manner. The slight additional disadvantage of removing the cam-shaft for the purpose of replacing cams, or for any other reason, due to the fact that the bull-wheel cannot first be removed, is more than offset, in my opinion, by the advantages that the 4-post construction affords.

### Height of Discharge

By height of discharge is meant the difference in level between the top of the die and the bottom edge of the discharge surface of the screen. A high discharge tends to retard the escape of the pulp from the mortar; increases the opportunity for the gold to be taken up by the quicksilver in the mortar because of the delay in the escape of the pulp; and it also promotes sliming, which in some ores is very undesirable.

To prevent the sliming of such ores, and at the same time free the gold so that it may amalgamate, a low discharge may be used with a finer screen. This will cause the ore to be crushed finer, freeing the gold from the rock, thus aiding amalgamation, while at the same time affording opportunity for a rapid discharge of the pulp, lessening the liklihood of sliming, which usually results when the pulp is held in the mortar by the high discharge.

When the best height of discharge for any particular ore has been learned by trial, and it can be learned in no other way, this height of discharge should be maintained as nearly as possible. This may be done by the employment of narrow strips of wood under the chuck-blocks. These are removed, one at a time, as the die wears down. It is usual to make these strips about 1¼ in. in thickness.

### Screens

There are a great many kinds of screens on the market, some of them most excellent, too, but after all it is difficult to get a screen that is generally better and cheaper (that is, cheaper for the tonnage crushed through them) than the old-fashioned tinned needle-punched screen. It is a good idea to experiment with a variety of screens, for with certain ores some screens give better results than with others. For instance, a flinty ore that under the stamps breaks into splinters and flaky fragments, will discharge better through a slotted screen, or even one of woven wire, than through a needle-punched screen. Such ores, however, are uncommon.

For granular ores the old-time tin screen is good enough, and records of ½ to ¼ cent per ton have been frequently made with them, and if they are properly treated before being tacked to the screen-frame, and then suitably mounted, the life of the screen will be prolonged and usually will be all that could reasonably be asked. The tonnage cost will be found to be quite as low as with any other kind of screen, and lower than with some others. Before placing the tin screen on the frame the sheet should be held over a bright fire, such as can easily be produced in any blacksmith's forge, and heated to redness. This burns off the tin and anneals and toughens the iron. When burning off the tin keep the screen in motion so that the heat will be applied evenly over the entire surface, taking care not to burn the metal as this damages it and its life will thereby be greatly shortened, for it is almost certain to break long before it is much worn.

To make any battery-screen more enduring, place strips of thin sheet-packing about an inch in width between the screen and the wood of the frame and the screens will last much longer, thus saving in the cost of the screen and in the time required to fit them to the screen-frame. Always buy those tin screens having an unperforated edge on both sides. Tin screens are mostly made in Germany and are made in large and small sheets. Mill screens made by cutting up large sheets are unsatisfactory, as at least one side has no selvage, and that side will quickly break after being put into service.

### Liners

All mill mortars should be provided with liners, and of late years all well-designed mills are thus equipped. Old mills not thus arranged may be provided with liners of some sort. I have had liners made of ⅜-in. steel plate to place in the mortars of a mill that were badly worn on all sides. These plates answered the purpose admirably, as well, in fact, as cast-iron liners would have done. Many old mills are without liners and the mortars are, in consequence, badly worn and daily become worse simply because the mill man does not know that he may remedy the difficulty by the exercise of a little ingenuity in making room for liners.

Mr. W. J. Loring, in Trans. A. I. M. E., Vol. XXVIII, 1898, thus describes the condition at one time in the Utica mills at Angels Camp, California, and the manner in which he overcame the difficulty: "The mortars in the mill were not lined, in fact, were not made for lining. After using them for several years it was found necessary to do something very quickly, as each end was worn, just above the dies, to ⅜ in. in thickness, which, of course, would not stand a great while. These stamps were set 10 in. between centers, using 8½-in. shoes, and leaving a space of 1½ in. between each two shoes. The dies, 5 in. in height, up to that time, had a life of 59 days, the life of the chrome-steel shoes then used being 191 days. The average number of stamps running per day for 333 days in 1896 was 57 out of 60, and they crushed 273 tons per day. In order to line these mortars I found it necessary to reset the stamps, using a guide 9¼ in. between centers, and leaving ¾ in. between the stamps. In this way 1½ in. was gained at each end of the mortars, allowing room for an end liner, which served as a key to the front and back liners. The back was filled with wood, carefully fitted in place, with the liner outside, saving considerable weight in unnecessary iron. This back lining is 13 in. high and stands at 77½ deg., the foot being 1½ in. from the base of the die, which causes the rock, as it is fed into the mortar, to fall on the die. These dies are made with 8¾-in. face, while the shoes have but 8½ in. This I have found to give better results than when both shoe and die are the same size, for the reason that the stem guides are bound to wear, allowing the stamp to swing. A play of ⅛ in. in the guide will allow the stamp to swing much more at the shoe, causing the shoe to overhang the die. Now, by having the die cast ¼ in. larger than the face of the shoe, we utilize the full crushing surface of the stamp. On the other hand, if the shoe and die have a greater difference in diameter, the one having the larger diameter will cup in wearing, causing a loss in efficiency. After making the above changes the mill ran 320 days; average number of stamps per day 59; average number of tons crushed per day, 296; average life of 5-in. cast-iron dies, 120 days; average life of manganese steel shoes, 296 days."

It will be observed from the above that the life of the dies was doubled, and that of the shoes increased by 50 per cent, and that the tonnage crushed was also materially increased by lining the Utica mortars. It would seem that there is a decided advantage in setting the shoes as close as it is safe to set them without interfering, but in doing this it is very necessary that the guides be in first-class condition, not having too much play, or they will interfere and stamp-heads, and sometimes bosses, will be knocked off. The longer life of shoes and dies may be attributed to the better protection they received by having the ore fall directly on the dies, and the increased capacity to this same cause, and to the narrowing of the mortars by inserting the liners.

Where possible shape and fit liners so they can be inverted when one edge is worn, thus getting the full benefit of the value of the material of the liner, otherwise it must be thrown away when only half worn.

### Width of Mortar

For rapid crushing use a narrow mortar. For ore that amalgamates with difficulty use a wide mortar, which discharges more slowly and gives the gold a chance to amalgamate, but do not forget in this matter what was said above under height of discharge and screen mesh. It is not necessary that the back of the mortar be the same distance from the edge of the die, as the distance from the opposite side of the die to the screen. The crushing capacity of a stamp-mill will be found to have about reached the maximum with a given screen and height of discharge when the distance from the die to the back liner is about 2½ in., and from the front edge of the die to the screen about 5½ in. The back liner should incline backward at 75 to 77 deg. Under no circumstances overfeed the mortar for this not only clogs up the screen, thus decreasing capacity, but it also endangers the screen, which is likely to be broken.

### Stamps and Cams

The higher the drop of the stamp the greater the splash and the more rapid the discharge, but there are limitations to the height of drop when speed of revolution of the cam-shaft, which controls the rapidity of drop of the stamps, is considered. I have known stamps to drop 110 times a minute, using double-arm cams, but the height of drop was only 4½ in. With single-arm cams a still more rapid drop is attainable without danger of camming, but single-arm cams are seldom if ever seen these days, though they were quite common in the early history of milling in California. I doubt if one can be found in the State at the present time.

In the early days those favoring the single-arm cam claimed for it that by its use it is possible to bring the cam-shaft nearer to the stamp-stem, thus permitting the commencement of the lift of the stamp to begin closer to a point directly over the center of the cam-shaft. I do not quite follow this reasoning, for I can see no reason why a cam-shaft equipped with double-arm cams may not be brought as near the stamp-stem as one having single-arm cams. In 1867 there was a mill at Austin, Nev., known as the Mettacom mill. It was equipped with single-arm cams. The stamps, weighing 900 lb., dropped 10 in. from 98 to 105 times a minute, and it was officially reported by Dr. R. W. Raymond that it ran at this rate for months and never broke a cam. It was a dry-crushing mill, and was built with unusual care for those early days.

Cam-shafts should be of liberal size—5 to 6 in., according to the weight of the stamps and speed of running. Cam-shaft bearings should be broad—10 to 12 in. Cast-iron covers for shaft boxes are unnecessary, but some mill men tack a piece of canvas to the battery-post in such manner that it will cover the box and keep grit out of it. Some mill foremen do not even babbitt the cam-shaft boxes, preferring smooth iron bearings. If the boxes are not well lined up and are babbitted the babbitt-metal is certain to break up from the concussion of the falling stamps, and the pieces of broken babbitt will usually drop down into the mortar, contaminating the amalgam and interfering with amalgamation.

### Temperature of Battery Water

A great deal has been written on this subject, but I think the majority are agreed that a temperature of 50 to 60 deg. F. gives the best results in plate amalgamation. If below 50 the mercury is too cold to do the best work, and if above 60 it is too thin and is likely to form small globules on the outside plates, which accumulating, may run off the plate, and if not caught in a mercury-trap at some point below, is lost. In the summer months, when the battery water may get warmer than 60 deg., it may be reduced in temperature by pumping it up into a cooling tower, where, in falling through the screens the temperature is lowered several degrees by the rapid radiation of the heat.

### Amalgamating Plates and Tables

Here is another subject over which there is great divergence of opinion, that is, the grade and manner of arranging the outside amalgamating plates. The differences of opinion are principally over the following: Divided plates vs. single sections; drops in the plates vs. no drops; raw copper plates vs. silver-plated copper plates; fixed plates vs. those that are movable and methods of cleaning up.

I never could see any advantage in divided plates. If the entire stream of pulp from a mortar be diverted from the whole surface of a plate to half that area, the result most likely to follow is the scouring off of amalgam already deposited there with very little deposition of new amalgam during the period of overloaded plate.

They who think divided plates the proper thing will, perhaps, argue that the time saved in dressing the plates amounts to more than the loss of the gold. With this argument I do not agree. In the first place there is the danger of the loss of gold already on the plate, and to this may be added the probability that little amalgamation takes place on the overloaded plate. The mill men are paid by the day and therefore their time would be as valuable doing something else. I think most mills have insufficient plate area and a division of the plates results in making a defect worse, and for this reason divided plates are undesirable. There may be places where they would be an advantage, but I have never seen such a place. Some think that divided plates should be used where the ore is very high grade and plates require to be dressed frequently. I should think that the losses would be greater where rich ore was being milled than where the rock was low grade.

Drops, or steps, in the plates, if not too high, are advantageous, as they have a tendency to keep the quick bright and to break up any small balls of sulphides and amalgam that sometimes form and roll away down the plate and are lost unless caught in a mercury trap or on the concentrators. Drops of ½ in., or at most not more than ¾ in., will be found to result in an accumulation of amalgam immediately beneath the drop.

Since this is a well-known fact I have sometimes thought that it might be a good idea to arrange the entire plate area with this fact in mind, constructing the plates of narrow strips of silver-plated copper plate arranged in a series of drops each ½ in. or ¾ in. in height. Make the strips 3 in. wide. If this were done it is quite possible the grade could be lessened from 1¾ in. per foot, which is about the average grade of mill-plates, to ½ in. per foot.

This arrangement in a table 12 ft. in length would give 48 strips each 3 in. wide, and 47 drops of ½ in. each, a total of 23½ in. in the drops, plus a grade of 6 in., in the 12 ft., making a total fall of 29½ in. This would give the series of plates an angle of about 12 deg. The amount of grade, whether ½ in. per foot, more or less, should be determined by experiment. The series of plates could be arranged in sections, say 18 in. each, and so constructed that they could be removed from a frame in which they rest and taken to the clean-up trough for the removal of the amalgam.

There are many who will at once condemn this idea, if for no other reason, because it is something new and untried, but it seems only rational to think that if drops in mill-plates at intervals of 2 to 4 feet are advantageous (and it is well known that they are, as amalgam collects in greater amount just beneath the drops than on the plane surface of the plates), then mulitple drops would collect amalgam at as many places as there are drops, and they would therefore be an advantage.

I recently saw a patented amalgamator of cast-iron circular segments arranged in a series of descending steps, and it is said to be an almost perfect amalgamator. It has no copper plates at all, but quicksilver is placed in the annular depressions which form each step of the device, and it is in these that amalgamation takes place.

In these days there are few who will claim any advantage for raw copper plates over those that have been electroplated with silver though when these latter were somewhat of a novelty there were many mill men who candidly expressed a preference for raw plates, and adhered to that idea for many years. Raw copper, if pure and well annealed, makes an excellent plate after it has been broken in, that is to say has accumulated a good coating of gold-amalgam which the mill man does not scrape off with a steel chisel each time he cleans up, exposing the copper, and making it hard to again get the plate in good condition.

As to the matter of the grade for mill plates, no arbitrary grade can be prescribed. Each mill man must work out this problem for his particular case at each mine, or with each different ore, for there is a vast difference in ores, and the facility with which they will amalgamate. Some ores require a heavier grade than others for their proper treatment by this method. Well designed plate-tables will be provided with means for changing the grade, either by the use of adjusting screws or by means of wedges. This will permit some latitude in the grade of the plates. The grade most commonly given plates in California mills is from 1½ inch to 1¾ inch per foot of the plates, not counting any drops that the plate may have. In a few instances the grade is heavier than this, being sometimes as much as 2½ inches per foot. This is very heavy and may not give the best results. Generally speaking, the proper grade is that which will keep the plate free from accumulations of sulphides, but if too heavy the rushing sands will scour the plate. A series of experiments will soon determine the proper grade for any particular ore.

The last thing: fixed or movable plates, is a matter of less consequence than some of the other things here referred to. Undoubtedly it is an advantage to be able to stand up in front of a mortar when placing shoes, dies or liners, or when removing the sands from the bottom of the mortar, instead of kneeling on a board thrown across the table. The tables can be built with a movable section at their upper ends, next to the mortar. This section, which should extend the full width of the plate-table, need not be more than 30 inches wide in the direction of the flow of the pulp. Its upper end should pass beneath the lip of the mortar, and the lower end extend out over the upper end of the fixed portion of the table, which it is best to have securely fastened to the floor. Such an arrangement as here described greatly lessens the hardship of working in the mortar box for any purpose whatever, and as it expedites work is economical and should be provided. When it is to be moved back out of the way, the men can pick it up and lay it over the stationary table.

As to the use of chisels on mill-plates when cleaning up, I see no objection to the practice if the chisels are handled with good judgment by the mill man, but it is injurious to the plate to dig into it with the sharp corner of one of these chisels made by bending an old rasp into the form of a hoe, or gouging the plate in any manner, as I have frequently seen done, in the effort to secure a little more amalgam. Even one of these chisels, ever so vigorously handled will not scrape gold amalgam from a silver-plated copper plate where there is none to be had, though I have often seen it tried, even sweating with hot blankets and scalding water, to say nothing of the gasoline torch. This latter practice is very bad, as it warps the plate and unfits it for further service, and its employment can only be justified, if ever, in making the last cleanup that it is ever expected to make on those plates. I have noticed, however, that the damage to mill plates is usually done in those mills where amalgam is disgustingly scarce. I have found that there is no instrument more satisfactory for cleaning mill plates than the glazier's putty-knife. It is broad, pliable, and easy to handle and will take up amalgam as well as any other kind of knife or chisel I have ever seen used for this purpose, and it does it, too, without injury to the plates.

When good ore is milled for a long time in any mill, the plates always absorb more or less gold, and in time they become rich with it. This is a subject, too, that has been frequently discussed. However, I will cite but a single instance that came within the range of my own observation: In a certain mill that had been in operation for 11 years, a new manager came in and as the ore those days was rather low-grade he decided to make a thorough clean-up, something that had never been done at this mill. The result was he recovered about $5,000 to the battery. Some of the gold came from old screenings, some from an old ditch-line through which tailings had run to waste, but by far the larger part of it was taken from the plates which for the first time were sweated and scraped with chisels. A large quantity of high-grade ore had been milled in this mill prior to this episode in its existence, and the new manager came from a district where it was the custom to gouge for every last cent in sight, each time clean-up day came around. It is needless to say in this connection that replating of the mill plates in that mill was of common occurrence. Also, it probably never again became possible to repeat the operation of the new manager at the mill where he made the big find in stored-up amalgam of which the owners had not the slightest suspicion until their attention was called to it.

### The Ore-Bins

There is a curious diversity of opinion as to the relative utility of flat-bottomed bins as compared with those having sloping bottoms. Some compromise by building bins that are partly flat and partly sloping.

A flat-bottomed bin affords storage capacity, but should the supply of ore run low, as soon as the angle at which the ore will run down to the chute doors by gravity is reached, men must be put in the bin to pick and shovel the ore down. When the flat floor is reached, if the bin be of good size, some of the ore must be handled at least twice to get it into the feeder chute.

To me it seems that the best place to keep a reserve of ore is in the mine and not in the mill bins. In a mill of 40 stamps, a bin that will hold 1200 tons of ore just as it is delivered from the cars or drops from the breaker floor, is a large bin—few of them are large enough to do it as ordinarily built. In the average California mill this amount of ore will keep the mill of 40 stamps supplied for not longer than six days, while the amount that will run from a full bin to the chutes by gravity is usually not greater than 700 tons in a bin of this size, leaving 500 tons to be shoveled in the event of the supply from the mine running low.

Flat bins are, perhaps, easier to build, but they require more lumber than bins having a sloping bottom. Rock will run quite freely on a slope of 40 degrees, if not clayey, and will come to a state of rest at 35 or 36 degrees, the angle varying somewhat with the material. If the bin is built with a bottom having a slope angle of 35 degrees a few inches of ore will lie on the bottom and thus protect it from the abrasion of rock falling from above. The small amount of ore lying on a slope of this kind can easily be worked down in case it is needed.

When an ore-bin of any shape is filled the movement of the ore at the front of the bin appears to be vertically downward toward the chute door. The result of this movement of the ore is to wear out the planks of the bin for a considerable distance (3 or 4 feet) immediately above the chute door. This may not be noticed at first, but in time it will be seen that the continued abrasion of these places will eventually cut the plank lining in two. This may be avoided by spiking sheets of steel—old turn-plates from the mine, the sides of worn out cars or skips, or anything else of the kind that will afford protection to the lumber of the bins. This protection costs nothing but the trouble of putting it in and will save considerable expense in relining the bin.

In some mills it is evident that it has been considered the most feasible plan to place the rock-breaker in the mill, on an independent frame of heavy timbers. This idea is all right, though it is better still to put the breaker in a separate building if possible. However, if the breaker is to be placed in the mill, and on a separate foundation, do not make the mistake of carefully tying this breaker-frame to the ore bins, and thus to the rest of the mill to give it solidity, nor for any other reason. I have seen this done and could never understand why any millwright, even a very ordinary one, would ever do such a foolish thing.

Where it is possible to conveniently so arrange it, two breakers in series, one set to break to 3 or 4 inches, the other to $1\frac{1}{2}$ inch or less, are desirable, as it increases the capacity of the stamps. This practice is becoming more common as its advantages are better understood. There are some engineers who contend that it is not economical to crush rock in breakers to a size smaller than $2\frac{1}{2}$-inch, but it is my opinion that the limitations in that direction should be determined by the character of the rock rather than by a fixed rule.

### Some Important Negatives

Here are some of the important things that should not be done:

Don't overfeed the mortar, but so adjust the feeder that it will supply the proper amount of rock, protecting the die and securing the largest capacity under existing conditions.

Don't turn too much water inside the battery, and add none at all on the outside plates.

Don't allow sand to accumulate in ridges and islands on the surface of the plates. If it does so promptly sluice it off, being careful not to use too strong a stream of water. If the sand again accumulates sluice it off again and then investigate the cause of it. It may be that the character of the ore has changed somewhat; that the water supply of the battery has been diminished from some cause, or it may be for some other reason, the cause of which must be discovered if possible. It may be that the grade of the plates will have to be increased a little.

Don't permit dark greenish, or bronze-colored spots to remain on the plates. Should any such appear, they are most likely to be due to the presence of soluble sulphates or free acid in the ore or water, or to the presence of some mineral not heretofore noticed. Grease also causes spots to appear on plates, and so does lead or babbitt-metal in the battery. Antidotes for these spots are: Strong solution of salt (NaCl), solution of potassium-cyanide, sodium amalgam, and not the least, a vigorous scouring of the plates with mercury and a suitable cloth. The proper remedy must often be determined by trial, but the last one above suggested is often worth as much as all the others combined, and is a wonder in securing good results.

Don't imagine the mill will run itself after it has once been adjusted, for it will not. Don't neglect the battery. Keep close watch over the entire line, both stamps and plates, that anything that may be going wrong may be quickly detected and the proper remedy applied.

Don't gouge plates with steel chisels to secure amalgam where none is to be had, it is bad for the plates and sometimes for the mill man.

Don't fix an arbitrary time for dressing plates. Dress them when they require it, and in some mills this is often.

Don't lay all the difficulties of amalgamating onto the ore, or on the machinery. It may be the water used in the battery that is at fault, particularly if the water be from the mine. I have known of a mine being condemned because the mill men could not amalgamate the gold, and some time later this same ore was hauled away to a custom mill and gave excellent returns and was found to be free milling to an unusual extent. Inquiry developed the fact that the water used in the former trial was from a mine in which there was a noticeable amount of arsenic.

Don't be afraid to have plenty of plate area. If gold can be taken from the last foot or two of plate the probability is that some gold is escaping the plates altogether, and more plate surface would be advisable.

Don't imagine you know it all. Study the operating conditions of your mill and see if they cannot be improved. In many cases they can be, Be wide awake, take one or more technical papers and keep posted, as the saying is, as to the latest and best practice. Often failure has resulted from lack of knowledge of some simple thing unknown in your own experience or in your district, but which is well known elsewhere.

Berkeley, California.

## Blast Furnace Blowing Apparatus

BY J. E. JOHNSON, JR.

The power first applied to blowing furnaces was that of water wheels, but something over a generation ago these passed out of use except at very small plants working under peculiar conditions, on account of the lack of water powers of sufficient capacity to drive furnaces with the increasing volumes of wind desired and increasing pressures which those volumes necessitated. This brought about the introduction of the steam engine for blowing purposes. The number of types of such engines, and the method by which they were applied to blowing purposes was almost unlimited.

About thirty years ago one type became predominant and held the lead for a long term of years. This is known as the long cross-head type, it consists of a vertical steam-cylinder with a vertical air-cylinder immediately over it, both pistons being connected to the same piston rod. The shaft passes immediately underneath the center of the steam cylinder with a fly-wheel at each end just outside the bed-plate which supports the whole. These fly-wheels carry crank pins exactly in line with one another so as to act as one.

The cross-head is fastened to the piston rod midway between the two pistons and extends parallel with the main shaft far enough for the wrist pins on its ends to come in line with the crank pins in the fly-wheels. The housings which support the air cylinder from the bed-plate are cut out in the center so that the cross-head can pass through and carry on each side of the opening the slides which guide the latter and take up the horizontal component of the thrust of the connecting rods.

Modern designs of this type of engine are shown in Figs. 1 and 2. This engine has the advantage of securing a direct transmission of the stresses arising in the work of compression directly from one cylinder to the other, and also of having its pistons move in a vertical line and therefore avoids their dragging on the bottoms of the cylinders with resultant friction and wear, a condition which at one time was considered unavoidable with horizontal engines.

This engine is also compact, it requires only a small foundation and small space in the engine house. It is under the disadvantage of requiring two connecting rods, and of requiring very careful workmanship in securing the absolute correctness of alignment of the two crank pins. It also labors under the disadvantages in regard to supervision to which all vertical engines are subject. The advantages were long sufficient to outweigh the disadvantages and this type of engine held an absolutely predominant place for a long term of years, and while changes in the conditions have brought about the development of many other types, these engines, when of modern design and economical type, are not only kept in use but new engines of this type continue to be built in considerable numbers. It is, therefore, with the development of this type that the modern blowing engine has its real beginning.

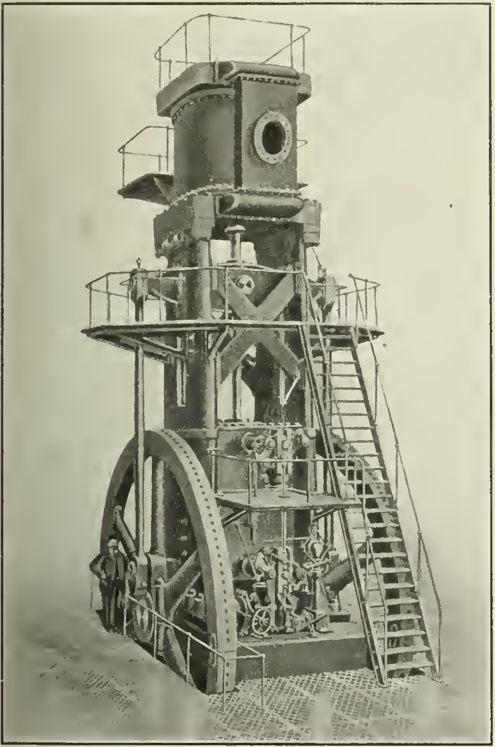

FIG. 1.—SOUTHWARK VERTICAL LONG CROSSHEAD BLOWING ENGINE

At the time when these engines obtained their predominance outputs per furnace were small with consequent small requirements for volume of blast and pressures were quite low, probably, on the average, less than one-half of what they are to-day.

As a result the power required per furnace was small and economy as I pointed out in the last article was a factor almost absolutely ignored. The small blast volume required made it possible for few engines of moderate size to supply the blast required for a furnace at a very moderate speed. Hence, there was little or no demand for high speed to cut down the number and size of engines required.

Under these conditions engines were always fitted with some type of self-actuating air valves, in which a slight difference of pressure within and without the cylinder operated both the inlet and the outlet valves in the required direction, and when this difference in pressure was ended and then reversed, as the piston reached the end of its stroke and started on the return, these valves were closed by the return currents of air so set up.

With low pressures and moderate speeds these conditions of operation produced no bad results, especially as the pressure and temperature to which the air was raised by compression were low and therefore valve faces and piston rings could be made of leather and wood respectively, or of other natural fibrous materials. These materials, however, while perfectly satisfactory at low temperature, undergo chemical change with increasing rapidity as the temperature rises and so the time came, as pressure increased, when such materials could no longer satisfactorily be used for these purposes.

This forced the substitution of metal faces for these valves and thus emphasized the two difficulties with automatic valves, the understanding of which had gradually come to pass. First, if these valves are operated entirely by the currents of air which pass through them, they do not seat themselves until these currents are reversed in direction, and then are brought to their seats with a violent shock at any but very low speeds. As long as leather could be used this shock was much cushioned by the leather, but when metal faces became necessary operation under these conditions became increasingly difficult.

Second, the area within these valves on which the excess pressure operates tending to lift them from their seats is less than the area without them tending to hold them closed, by an amount equal to the area of the seat itself, which must always be a considerable percentage of the total area. Therefore, the pressure within the valve must always be greater than the pressure without it, in the inversed ratio of the internal and external areas, before the valve will open. This leads to a delayed operation of the valve and necessitates much greater difference between the internal and ex-

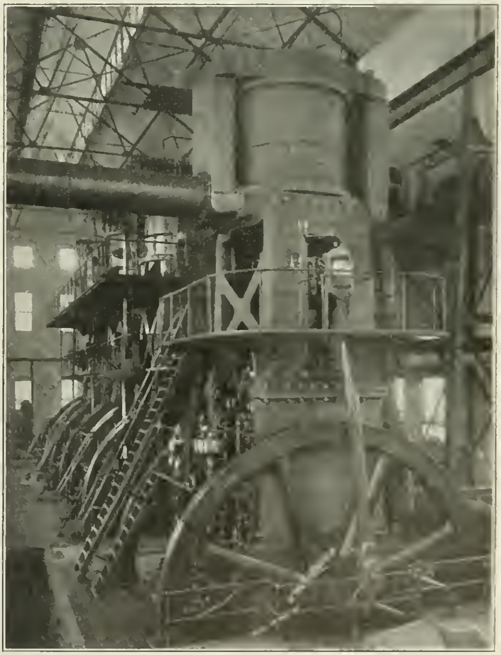

FIG. 2.—INSTALLATION OF "MESTA" LONG CROSSHEAD STEAM BLOWING ENGINES

ternal pressures than would otherwise be necessary with corresponding loss of power.

If in order to overcome the difficulty of having the valves slammed hard against their seats by the reversed currents, a weight or spring was applied to them to force them to their seats, the pressure due to this weight or spring must be added to the difference between the internal and external pressures, with corresponding further loss of power. It is obvious that as pressures rose and speeds increased these difficulties must be augmented.

There were also other conditions of great importance to be met. First, the clearance should be kept small so that as nearly as possible all the air displaced by the piston may be driven out through the discharge valves instead of simply being compressed into the clearance space, and then re-expanding at the beginning of the next stroke, to the exclusion of air which should be taken in from outside.

Second, the area of the valves must obviously bear a definite ratio to the area and speed of the piston so that a valve area which is quite sufficient to permit relatively complete filling and ready discharge of a given cylinder at a low or moderate speed may be quite insufficient for the same cylinder at a higher speed. It must be remembered particularly in this connection that these losses are frictional and, therefore vary as the square of the velocity, so that a cylinder which will fill with two ounces of suction at thirty revolutions will require one-half a pound at sixty, and a pound and one-eighth at ninety.

To meet as well as possible these conditions of low clearance and large area, a great multiplicity of valves, both for inlet and discharge were adopted, and this was standard practice for many years, there being more than a hundred such valves in each end of an air cylinder of moderate size, in some designs.

With increasing rate of driving came increasing pressure, and this brought about another difficult condition. It modified the shape of the indicator diagram for the air cylinder very much for the worse, from the point of view of the engine. With a blast pressure of four pounds the piston travels only about 20 per cent. of its stroke before the air is compressed to the required pressure and begins to flow through the discharge valves so that with reasonably good design of valves, the work done upon the air cylinder was quite uniformly distributed throughout the stroke and subject to a minimum of variation. With a blast pressure of twenty pounds the piston travels more than 50 per cent. of its stroke against a pressure which rises constantly more rapidly, with the result that about three-fourths of all the work of the stroke is done in its last half.

On the other hand, the older types of uneconomical steam cylinders used but little expansion and so the steam pressure was but little lower at the end of the stroke than it was at the beginning, and the drop which took place was quite gradual with no sharp or sudden changes.

The demand for increased economy grew, as has been pointed out in the last article, and this could only be obtained by one means, much greater completeness of expansion of the steam. This means that under ordinary conditions nearly one-half of the total work of the stroke must be developed in its first quarter, exactly the opposite to the way in which it is consumed, the greatest portion, as we have just seen, being expended in the latter portion of the stroke.

Some form of equalizer has to store the surplus work done in the steam cylinder in the early portion of the stroke, and give it out in the latter portion, and this equalizer is the inertia of the fly-wheel and of the reciprocating parts, but it is obvious that in a running machine which must have a certain amount of play in its moving parts a complete reversal of the stress from one direction to the opposite, somewhere near the middle of the stroke, could not contribute to its smooth and easy working.

It will be seen from the above that the conditions under which the blowing engine worked in the early days of the long cross-head type grew steadily worse with the development of modern furnace practice. As a consequence of these conditions it is probably safe to say that, next to the furnace itself, blowing engines have given more trouble and furnished more difficult problems to furnace builders and operators than any other portion of the equipment.

## Air Valves

To meet the increasing difficulties to which changing conditions subjected the automatic types of valves many designs of positively actuated valves were brought out, of which the test of time has left but few, and it is not possible in a single chapter to treat any except those which have had some considerable degree of industrial success.

### CORLISS VALVES

The Corliss or semi-rotating valve had proved its serviceability, its relative ease of operation, and its tightness under long continued wear, by almost half a century of successful use in the steam engine, at the time when the development here under discussion began, therefore it is not surprising that this valve should have been one of the first applied to air cylinders. In its earlier form it was applied in almost the identical way that it was in the steam engine, except that the inlet valve in the air cylinder corresponds to the exhaust valve in the steam cylinder, as does the discharge valve of the air cylinder with the inlet valve of the steam cylinder.

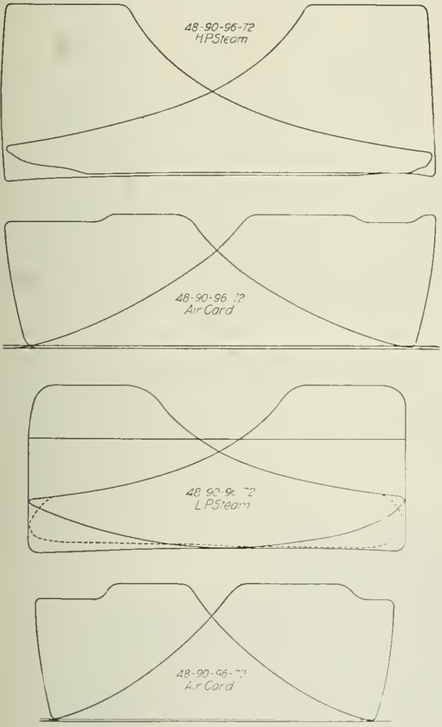
A glance at the indicator diagrams, Figs. 3 and 5, showing steam cards, Figs. 4 and 6 showing air cards, will show that these are of the same general type and shape but one is traced in one direction and the other in the opposite. One represents positive work and the other represents negative work, or energy absorbed. So the base line of one represents spent fluid discharged, and of the other incoming fluid to be compressed.

The inlet line of the air cylinder changes but little with changing conditions, that is to say, the times at which the inlet valve opens and closes are only slightly altered by changes in speed or pressure.

Theoretically the proper time of opening is changed slightly because the greater quantity of air in the clearance space at higher pressures expands to a greater volume at atmospheric pressure, and in order to recover all the energy due to the complete re-expansion of this air the inlet valve should not open until re-expansion brings the pressure of this clearance air down to that of atmosphere, which, of course, means that the inlet valve should open somewhat later with high pressures than with low. But no practical or even appreciable loss is experienced under any ordinary condition, by having this point of opening fixed at the point to suit normal conditions.

For these reasons the inlet valve is positively connected to the eccentric and opens and closes at predetermined points in the stroke. The discharge valve on the other hand ought obviously to open at a different point with four pound pressure from what it would for twenty, and it was long thought that it was necessary to put the opening of this valve under the control of some type of trip mechanism, akin in principle to the Corliss dash-pot, which was released by a small auxiliary cylinder in direct communication with the end of the main cylinder, so that as the pressure in the latter rose, the auxiliary piston tripped the releasing gear and the dash-pot pulled the valve open.

It was left for Mr. B. V. Nordberg, of the Nordberg Manufacturing Company, to point out that the loss by having the discharge open a trifle too soon was almost insignificant, in fact practically inappreciable even with very considerable changes in the discharge pressure, and he therefore builds blowing engines, in which both the inlet and the discharge valves are rigidly connected to eccentrics, timed to open and close them at the proper point for normal conditions. A clause in the contract for the first of these engines provided that if it should be found necessary, an automatic gear would be provided at small additional expense which would shift the point of opening of the discharge valves as the pressure rose, but the results from the engine in practice were almost absolutely perfect, and no conditions ever arose to cause regret at the omission of this automatic device.



FIGS. 3 TO 6.—STEAM AND AIR CARDS

Corliss valves have several great advantages. By a suitable design of valve gear they can be made to perform most of their travel at a time when the pressure on their opposite sides is approximately the same, so that they can be moved with a minimum of power and of wear, and owing to the "dead travel" obtainable with a proper design of wrist plate are almost stationary when the unbalanced pressure upon them is considerable. They are held against their seats by pressure, and follow them down as they wear, with the result that their tightness in service under good conditions is well maintained. They also permit large port areas with minimum clearance.

On the other hand they require a considerable quantity of oil for proper lubrication, and one large set of engines with this type of valves so designed as to require an excessive amount of oil to keep them in operation was probably more responsible than any other one condition for their failure to develop into a leading type of valve. In spite of this fact at least one engine with valves of this type is known to the writer which has been in virtually continual operation for twenty-five years and is in first-class condition now.

### POT VALVES

The poppet type of valve had always been used for discharge valves and one of the first steps in replacing the Corliss valve for air cylinders was the introduction of a modified form of poppet valve which opens automatically, but is positively closed, an idea first brought out by the German engineer, Riedler.

This valve consists of a hollow steel pot drawn from a single piece of steel. This pot is from eighteen to twenty-four inches in diameter and of approximately the same depth, with a spherical bottom surface, the metal in it is about a quarter of an inch thick in the bottom, and three-sixteenths of an inch in the sides. This closes against a suitable seat in the cylinder head close to the piston. Inside of it works a plunger, sometimes this plunger is the same diameter as the inside of the pot in which it acts as a piston, sometimes the plunger is of smaller diameter.

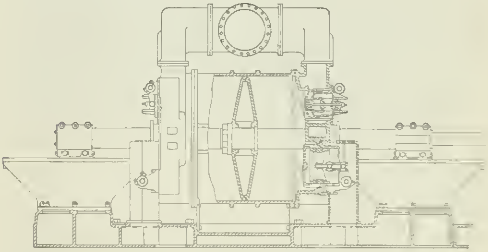


FIG. 7.—REYNOLDS' POPPET VALVE

This plunger is operated by a rock shaft driven from an eccentric so timed that the plunger forces the valve to its seat an instant before the crank passes the center and before any return current of air can be set up from the receiver back into the cylinder. The plunger is then withdrawn and the valve is held to its seat by the excess pressure within it, since it is provided with small holes around its circumference, just above the seat, which put it into constant communication with the air receiver, and which permit the escape of the air between the plunger and the cylinder, thus helping to bring it to its seat gently and without shock or jar.

One of these valves is shown in the upper portion of the right-hand end of Fig. 7. This type of valve has remained the predominant one throughout the period of supremacy of positively operated valves. The original form of this design was the invention of the late Edwin Reynolds.

Various types of air inlet valves were tried, all designed to keep the clearance down to a minimum and yet give ample area for the admission of air, not only to keep down the suction but to secure the complete filling of the cylinder before the beginning of the compression stroke.

Two of these designs were radical and interesting by their boldness. One was known from its inventor, Mr.

Julian Kennedy, as the Kennedy inlet valve. It consists, as is shown in Fig. 8, of a long slender cylinder passing entirely through both cylinder heads and the piston of the air cylinder, with suitable packing rings or glands in all three. This cylinder has near its upper and lower ends a system of ports cut through its walls on long spirals, one set for each end of the air cylinder. This valve is driven by an eccentric so that the ports in it are brought within the cylinder head during the admission stroke. Both ends of the valve are perfectly open to the air which passes in through its ends and out through these ports into the cylinder. The valve was properly timed to open and close correctly at each end of the cylinder.

Fig. 8 shows a design in which this valve is set on one side of the cylinder and presumably in this case there are two of these valves. In the ordinary design there was one valve in the center of the cylinder, and the air piston was driven was driven through two piston rods symmetrically spaced on each side of it, a design which has some merit.

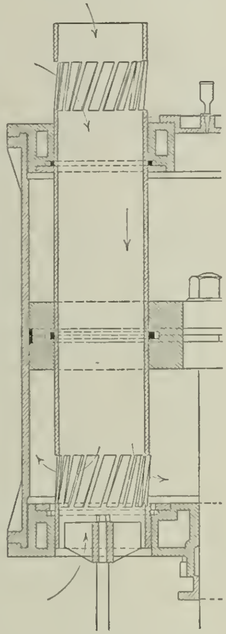

FIG. 8.—KENNEDY INLET VALVE

The other design was the invention of Mr. E. E. Slick, formerly chief engineer of the Edgar Thompson Works, now general manager of the Cambria Steel Company. This was still more radical. The whole cylinder was perforated at each end with a set of ports like those in the Kennedy inlet valve, and this cylinder was moved back and forth by a heavy rock shaft so that during each suction stroke these ports came within the inner surface of the corresponding cylinder head, these being rigidly held independently of the cylinder and making a sliding joint with it like the piston. This obviously gave the whole circumference of the cylinder for a port and yet the clearance due to inlet ports was absolutely nil. This arrangement is shown in Fig. 9, it has been successfully used for a number of years on large and particularly on high-speed blowing engines, but many engineers and furnace operators objected to the awkwardness of the principle involved in sliding cylinder weighing several thousand pounds back and forth through a travel approximating a foot at a rate of sixty, seventy-five, or more revolutions per minute.

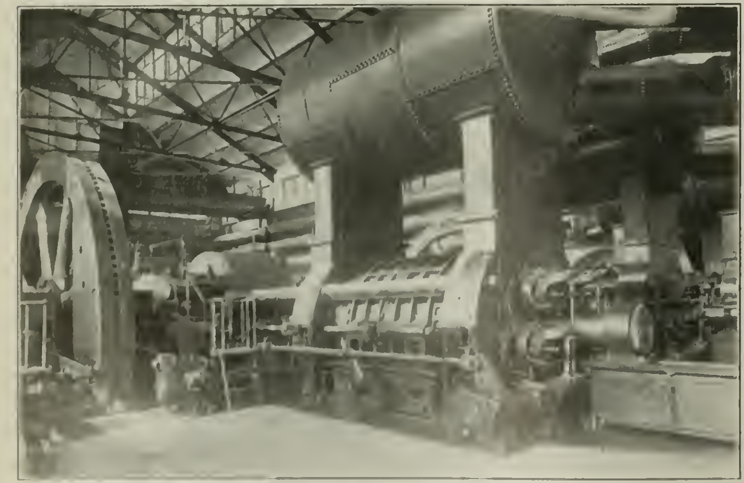

FIG. 9.—SLICK-BLOWING TUBS IN THE CENTRAL FURNACES OF THE AMERICAN STEEL & WIRE CO., CLEVELAND, OHIO

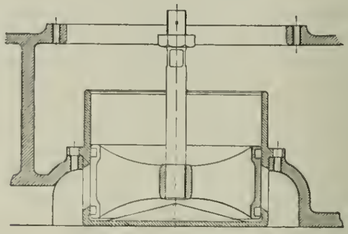

FIG. 10.—KENNEDY PISTON INLET VALVE

The Kennedy valve also was disliked by many engineers and operators because of the great mass of metal to be pulled back and forth through a travel of nearly two feet, and at speeds up to fifty or sixty revolutions, also to the three moving joints necessary in that device, one in the piston, and one in each cylinder head. On several occasions these valves became detached from their driving mechanism and owing to their inertia, due to their weight and high speed, they generally made a wreck of serious proportions under such conditions.

A modification of this valve has been very successful. This is shown in the lower half of the right-hand air cylinder head in Fig. 7 and by Fig. 10. It consists practically of one end of the Kennedy inlet working in a short cylinder set in the main cylinder-head.

The air passes in this case longitudinally through the valve and then outward through the ports in the sleeve which carries it, and so into the main cylinder. The only disadvantage under which this valve suffers as compared with the Kennedy is the slight increase in clearance necessary to carry the air from the ports in the sleeve into the cylinder proper.

The weight of the valve is only a small fraction of that of the Kennedy, and its travel is also much less, so that the inertia of this type of valve is almost insignificant in comparison with the inertia of the Kennedy valve and Slick valve types.

The construction is shown in the illustration.

### THE SOUTHWARK AIR VALVE

The Southwark Foundry & Machine Company had enjoyed for many years the reputation of pioneer builders of high-speed engines, having developed a system of balanced slide valves for the steam cylinder which could be put under the control of a governor, and permitted these engines to be operated at a higher speed than that attainable by any other type of large engine at the time when the modern development of blowing engines began. They also appreciated the advantages of high speed from a purely mechanical standpoint, notably in regard to inertia stresses and the beneficial effects which they could be made to exercise upon the running of engines. This is a subject which we shall presently discuss.

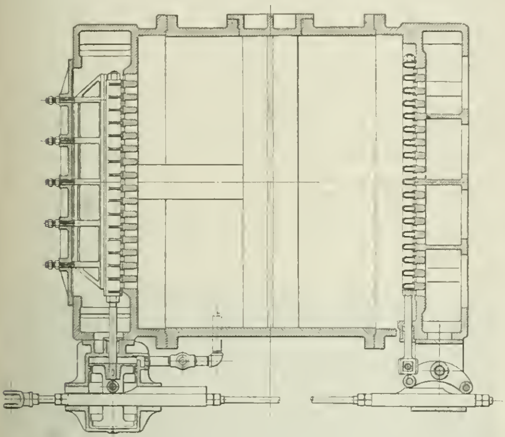

FIG. 11.—SOUTHWARK AIR CYLINDER SHOWING INLET AND OUTLET VALVES, WITH GEAR

These two conditions made it natural that the Southwark Company should desire to extend the benefits of their system of high speed engines to blowing engines, and they accordingly developed a system of positively operated valves arranged to open and close without shock and to provide ample port area for any speed at which blowing engines could be successfully operated. This system uses a multi-ported or a grid-iron valve both for inlet and outlet. The inlet valve is operated entirely by a cam driven by an eccentric. The inlet valve is on the inside of the head and is unbalanced because its movements take place only at times when the pressure on both sides of it is the same. The discharge valve is on the outside of the head and is balanced by a cover plate on its back. This valve is closed at the end of the stroke by a cam attached to the same mechanism as that which operates the inlet valve, but is opened by a small auxiliary cylinder in communication with the main cylinder, when the rising pressure in the latter during compression, equals that in the receiver.

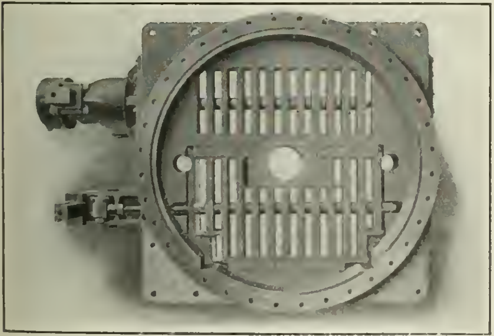

FIG. 12.—SOUTHWARK AIR CYLINDER HEAD, INSIDE VIEW

A longitudinal section is shown in Fig. 11, and views of a cylinder head with its valves is shown from within and from without by Figs. 12 and 13.

It is probably no more than fair to say that this system of valves was the earliest of any of the mechanically operated valves to be developed into its present condition and at the same time remain in general use. It is also probably fair to say that this valve was the first to be used in this country at the high speeds which are absolutely necessary with gas-driven blowing engines, and which are very desirable with many steam engines.

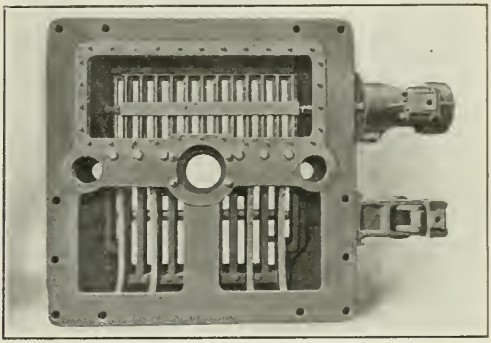

FIG. 13.—SOUTHWARK AIR CYLINDER HEAD, OUTSIDE VIEW

#### The Return to Automatic Valves

The last two or three years have seen a development in this field which brings us back almost to the starting point. The gas engine has received a great development in Germany and as the speeds at which it has to run in order to be successful are considerably higher than those customary with steam engines, the question of air valves has been one of great moment to the German engineers, and they have developed a system which modern workmanship and modern metallurgy has made possible.

Each valve consists of three concentric rings held together by radial bars or bridges, the whole being stamped from a single plate of thin special steel. This is fastened to a flat spiral (not helical) steel plate spring held to its seat by a hole through the center.

The valve seat consists of similar but alternately spaced concentric rings, the openings between which constitute the ports and are covered by the valve rings when closed.

The valve is extremely light in weight and requires but a slight lift to give full opening and its inertia is, therefore, very small.

For this reason the small tension of the flat spiral spring is sufficient to seat the valve at the proper time without adding appreciably to the air resistance in passing through it.

The principle of this valve is not essentially different from that of the poppet valve of fifty years ago, but the details of the design are such as to constitute the difference between failure and success under modern conditions.

The American patent on these valves has been bought by the Mesta Machine Company, of Pittsburgh, by whom they have been redesigned and are being introduced under the name of the Iverson Valve. These are shown in Figs. 14, 15 and 16.

The results with these valves in regard to providing the area necessary for inlet and discharge with minimum suction on the bottom of the indicator card, and minimum excess pressure on its top line, are claimed to be equal, if not superior to, the best of the mechanically operated valves. The clearance is small and the operation of the valves is noiseless.

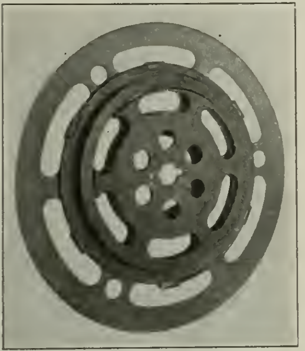

FIG. 14.—VALVE PLATE AND SPRING OF "MESTA" (IVERSON PATENT) AUTOMATIC PLATE VALVE

These valves have one advantage also which I should hardly have believed if I had not seen the results myself. In vertical engines the inertia of the eccentric rods, rock-shafts, and other mechanism for actuating the air valves is sufficient to cause some vibration in almost all engines, and in those of the steeple type this has in many cases been excessive. In cases where these valves have been substituted for mechanically operated valves, the entire absence of any moving parts except these light valves themselves, which only move a distance of an inch or two, eliminates this vibration.

I have seen engines running side by side, one vibrating almost dangerously and the other perfectly still. The manager who was then trying the valves out told me that the engine with the automatic valves had vibrated as violently as the other when it was positively operated.

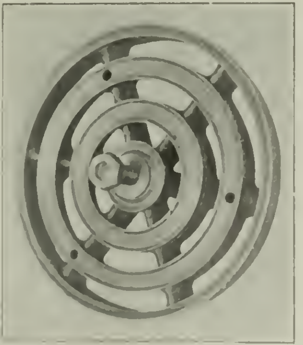

FIG. 15. VALVE SEAT OF "MESTA" (IVERSON PATENT) AUTOMATIC PLATE VALVE

It is probably too early in this new development to say what its ultimate results will be, but if the promise of the present is fulfilled we shall probably witness the elimination of much complicated and expensive mechanism from our blowing engines in the next few years.

### Methods of Compounding

The growth of a demand for economy in blowing engines, previously described, obviously required the introduction of compounding, to which at first sight the long cross-head type of engine did not adapt itself well.

The late John Fritz solved the problem by putting the high and low pressure cylinder of the compound side by side over the shaft in the position previously occupied by the single cylinder, and connected both piston rods to the long cross head, the position and parallelism of this being rigidly controlled by the connecting rods at its outer ends, by which the continually varying differences in pressures in the two cylinders were absorbed apparently without injurious racking stresses on the engine.

A single air-cylinder was used, as with the simple type of engine, its piston rod being connected to the center of the long cross head as before.

This type of engine, however, never received general favor, and, consequently, other types were developed which adapted themselves to compounding. The principal ones of these types are the horizontal cross-compound with tandem air cylinders, the vertical cross-compound with tandem air cylinders, known as the steeple type, the cross-compound horizontal vertical engine with horizontal steam cylinders working on two cranks at right angles with the air cylinders vertically over these cranks and driven by them, the quarter crank vertical engine with steam and air sides entirely separated except for the crank shaft which connects them, and the disconnected compounds.

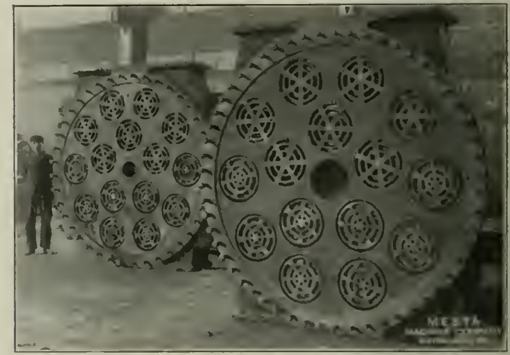

FIG. 16.—AIR HEADS EQUIPPED WITH "MESTA" AUTOMATIC PLATE VALVES (IVERSON PATENT)

Before we can discuss these different types of engines intelligently the subjects of the inertia of the reciprocating parts and engine friction must be briefly treated. The subject, as applied to the steam engine, will be found in any good treatise on that subject, but the steam engine is very different from any type of blowing engine in which the air and steam pistons are connected to the same rod, for the reason that all work generated in the cylinder, in the power engine, has to pass through moving parts, the cross head pin, crank pin and main bearing, into the crank shaft, from which the useful effect is delivered. While in the blowing engine where the steam and air pistons are rigidly connected to the same rods the energy generated in the steam cylinder is transmitted only through a rigid member directly into the air cylinder, except as has been pointed out that most of the work is generated in the steam cylinder in the early part of its stroke, and the principal utilization in the air cylinders occurs in the latter part of the stroke.

It is obvious that the excess not immediately utilized in the air cylinder must be stored either in the fly-wheel or in the reciprocating parts and given out again to make good the deficiency in the latter part of the stroke. The transmission of these excesses and deficiencies through running parts affects seriously the friction of the engine, which is important not only on account of the power so lost, but because the power lost represents destructive energy applied to the moving parts of the engine itself, and for economy of maintenance if not for economy of power, should be kept as low as possible.

It is probably true to say that the friction of a well built reciprocating steam engine is about 10 per cent. of its indicated horse-power at its rated load, and when running idle, but up to speed, the friction is about one-half of this, that is, about 5 per cent of its rated power.

It is obvious, therefore, that if we can take part of the energy developed in the steam cylinder and apply it directly without its having to pass through the running parts to the fly-wheel, we shall make a considerable saving in friction, and, consequently, in wear.

### INERTIA OF RECIPROCATING PARTS

This is not the place for an extended discussion of the subject of the inertia of the reciprocating parts, which is a mathematical problem of no mean order if it be handled completely and accurately. For our purpose, it is sufficient to say that the inertia of the reciprocating parts at the end of their stroke exerts a force equal to the centrifugal force of an equal weight hung on the crank pin, and in the same direction, that is, outward from center of the crank shaft. Starting at this value this inertia diminishes in the same proportion as the distance of the piston from the center of its stroke, at which point the inertia becomes zero. Then, as the piston approaches the other end of the stroke the inertia effect rises from zero to an equal amount in the opposite direction.

It is obvious that this inertia always acts outwardly from the crank shaft; that is to say, at the head end of the stroke it acts toward the head of the cylinder, and at the crank end of the stroke it acts toward the crank end of the cylinder. The fact that this force increases from zero at the center to a maximum at the ends, and then decreases down to the center again on a straight line diagram, should be emphasized, because it is often supposed by those who have not studied the subject that this force is exerted only at the end of the stroke. Nothing could be further from the fact.

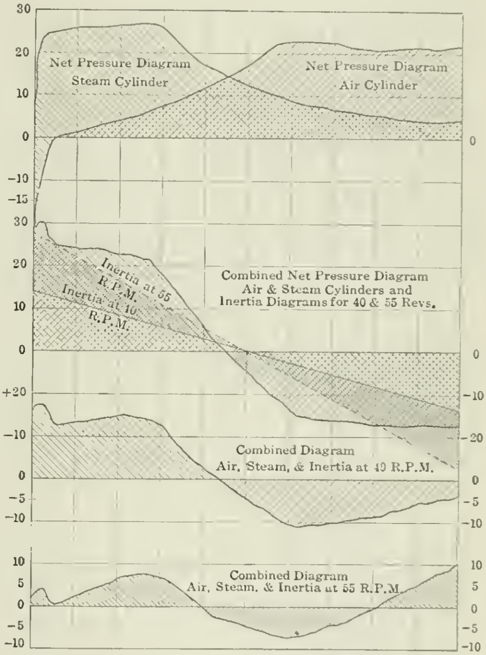
The statement of the exact proportionality of this force to the distance from the center of the stroke is exactly true only when the connecting rod is of infinite length, or when the slotted cross head or Scotch yoke is used, which, of course, is never done with blowing engines. With connecting rods of finite length the inertia effect is greater at the head end and less at the crank end than the amount stated, by that fraction of the whole which expresses the ratio of the crank-throw to the connecting-rod length. This, while a matter of some importance to designers, is not of sufficient importance for our purpose to necessitate its being taken into account, as the assumption of the straight line diagram for the inertia effect is sufficiently accurate for our purposes.

It will be obvious from what has been said that this inertia effect tends to absorb energy from the steam cylinder in the early part of the stroke, when energy is required to accelerate these moving parts, and to give it out again in the latter part of the stroke, when these parts are being retarded by the movement of the crank. This means that the reciprocating parts are taking up energy at a time when the steam cylinder has it to spare, and giving it out at a time when the air cylinder needs it.

In order to investigate this effect quantitatively in relation to the air and steam pressures, it is necessary to determine the total inertia effect and then consider it as distributed over the air piston as if it were a force of so many pounds to the square inch. Similarly, we can reduce the pressure of the steam cylinder in the ratio of its area to that of the air cylinder, and so put all three of these forces on the basis of a common unit, of pounds per square inch of air cylinder area.

Through the kindness of the William Todd Co., of Youngstown, I have obtained sets of indicator cards from the air and steam cylinders of steam blowing engines, and also similar cards from a gas blowing engine. They have also given me the rated speeds of these engines and the weights of the reciprocating parts, as well as the diameter of the various cylinders and the strokes.

These diagrams for a horizontal cross compound blowing engine with forty-eight-inch high-pressure cylinder, ninety-inch low pressure, ninety-six-inch air cylinders and sixty-inch stroke in common are those shown in Figs. 3, 4, 5 and 6.



FIGS. 17 TO 20—DIAGRAMS

These cards were taken to represent approximately simultaneous conditions in all the cylinders. The rated speed of this engine is forty revolutions, the weight of the reciprocating parts on each side is approximately sixty thousand five hundred pounds.

From these I have laid out what may be called the resultant diagrams of all three forces, that in the steam cylinders, that in the air cylinder, and that of the inertia—all reduced to pounds per square inch of air cylinder area, which are shown in Figs. 17, 18, 19, 20.

There are obviously four sets of such resultant diagrams for such an engine, one representing one stroke in each direction and on each side, but as all of these are more or less similar one will be sufficient to show the principle involved.

We first have to convert the diagrams as taken which represent the conditions throughout the cycle of one revolution in each end of each cylinder and convert them into "net pressure" diagrams for the steam and for the air cylinders by deducting from the pressure in one direction, the *simultaneous* pressure into the opposite end of the cylinder in the opposite direction, this subtraction being made in the algebraic sense. These two net pressure diagrams are shown in Fig. 17, the pressures of the air diagram being in the opposite direction to those of the steam diagram. Ordinates below the line represent pressure in the opposite direction to that represented by ordinates above the line.

We can obviously combine these two diagrams into one by subtracting the ordinates of one from those of the other in the algebraic sense. The result of this operation is shown in Fig. 18, which shows that the pressure is entirely in one direction during one-half of the stroke, and suddenly changes to the other near the middle of the stroke. On this diagram is shown, as a solid straight line passing through the center, the value of the inertia per square inch of air cylinder area, for forty revolutions, and in dotted lines that for fifty-five revolutions.

Remembering that ordinates of the inertia diagram above the zero line on the left-hand side of the diagram mean energy absorbed, and those below the line on the right hand side of the diagram mean energy given out, we can obviously deduct these ordinates from the net pressure ordinates of the combined diagram for air and steam, and the result will be the final net pressure transmitted to the crank pin. The result of this subtraction is shown in Fig. 19 for forty revolutions, while Fig. 20 shows the result which would be obtained on a similar basis if this engine were run at fifty-five revolutions instead of forty.

It will be obvious at a glance that the energy represented by the triangular area of the inertia diagram has been subtracted from the energy imparted to the fly-wheel in one part of the stroke and subtracted from that given out from the fly-wheel in another part of the stroke, the result being that the energy transmitted through the running parts at forty revolutions is only about one-half of that represented by the total work done, and would become an almost insignificant amount at fifty-five revolutions.

It may be thought that these considerations are too theoretical to be of practical importance, but I have seen large blowing engines in poor condition which would make a noise almost like steam hammers when running at a low rate of speed, but which would quiet down when the speed was increased until at a speed as high as the valve gear would stand they would run silently and well. Moreover, the Southwark Company has designed blowing engines on this principle for many years which have run as successfully as those of any other maker, and more successfully than those of some builders, who use much lower speeds, because they are afraid of the higher ones.

The Nordberg Manufacturing Company also has built blowing engines, some of them to the specifications of the writer, which were designed on this principle. They had a relatively short stroke, and ran at a high rotative speed, and so obtained the displacement of a much larger engine at a lower speed. These engines were properly proportioned as to the inertia stresses and ran with the most perfect smoothness and absence of all pounding and noise at high speeds, seventy-five and eighty revolutions, as well as at lower ones. These facts have a most important bearing upon the design of blowing engine to be preferred.

### The Disconnected Compound

The problem of compounding blowing engines has been solved in the case of several of the types of engines above described, by building two separate units, one containing the high-pressure steam cylinder, the other containing the low, these units being connected only by the steam receiver. These engines are thus enabled to run as compounds and enjoy the benefit of that system, and at the same time retain the flexibility due to small units, because each engine can be run separately. The high-pressure engine has two dispositions for its exhaust, one to the receiver and the other direct to the condenser, or atmosphere. Then, if the low-pressure engine is not needed, or needs repairs, it may be shut down and the high-pressure then exhaust-direct. Similarly, the low-pressure unit has a double source of steam supply, one the receiver steam from the high pressure, the other, live steam throttled through a reducing-valve, so that this engine can be run entirely independent of whether the high pressure unit is in operation or not.

This type of compounding has been applied to the horizontal tandem, the quarter crank vertical, to the horizontal tandem, and particularly to the long cross-head types of engines. In fact, for several years the long cross-head type of engine regained at least in part its old preëminence through the introduction of this system.

When this system is used one engine may be used on one furnace and the other on another, if desired. Where three cylinders are required to blow a furnace, as is not infrequently the case, six of these units, constituting three complete compounds, blow two furnaces, one complete unit on each furnace, the high-pressure of the remaining unit on one furnace and the low on the other. The arrangement of the valves is such that if one furnace is to be shut down, or if the blast be taken off for even a short time, the exhaust valves on the high pressure can be operated simultaneously, the receiver exhaust being closed while the direct exhaust is opened; the steam valves on the low pressure can be similarly operated so that either half of the unit may be kept going on its furnace irrespective of what the other unit is required to do. The governor operates on the high-pressure cylinder only and the cut-off of the low pressure unit is regulated by hand to bring its speed the same as that of the high pressure. This adjustment will hold for a considerable variation of pressure without very much variation from the desired speed on the part of the low-pressure unit, when both are in one furnace, and, consequently, blowing against the same pressure, but when the two units are used on different furnaces whose pressures vary in different ways, the conditions are not so simple and more frequent adjustment of the cutoff on the low-pressure unit is required.

The writer designed several years ago a means whereby these engines could be made to run at the same speed irrespective of the conditions under which they operated, but the manufacturers took no interest in introducing the device, and nothing was ever done with it.

### Review of Different Types of Engines

We may now review these different types of engines in the light of the general conditions set forth above, and pass on their desirable and undesirable characteristics.

#### THE VERTICAL QUARTER CRANK ENGINE.

This engine, shown in Fig. 21, is built in practically the same design by several of the best builders, and is not, as far as I know, recommended particularly by any of them. I shall not, therefore, do any injustice to any of these builders when I say that in my judgment this is the poorest type of blowing engine in regular use today. A certain measure of accessibility is obtained by the fact that it has no tandem cylinders, but it requires a considerable amount of space, a much larger foundation than a long cross-head engine of the same capacity, and an equal if not greater height, while its running parts are very inaccessible for handling with a crane.

The principal objection to it, however, is that it has two complete sets of running gear with their high first cost and maintenance, and that all the energy developed in the steam cylinder has to be transmitted through running parts into the crank-shaft and then from the crank-shaft through another set of running parts into the air cylinder. Taking the mechanical efficiency of a standard steam engine at 90 per cent and the mechanical efficiency of a crank-driven compressor at the same we have an efficiency in this engine of 81 per cent as against 91 to 93 per cent that may be and is secured in regular practice with the tandem connected machine. It is well to remember that this 21 per cent of friction loss as against 8 per cent in the other case, represents not only a loss of power but an expenditure of energy for destructive purposes which must reappear in the form of wear of two sets of heavily stressed running gear instead of one set lightly stressed.

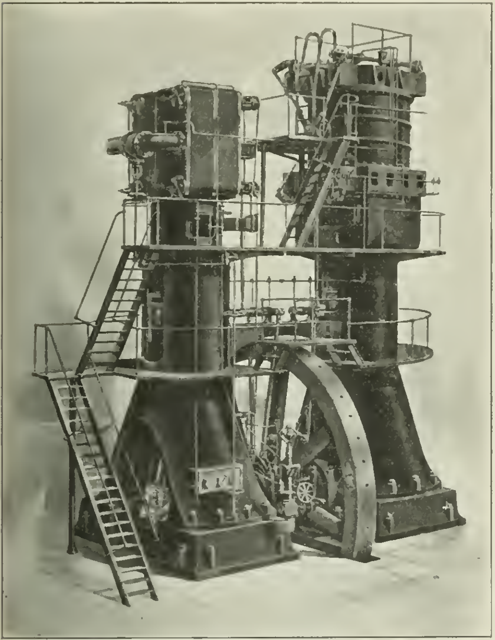


FIG. 21.—VERTICAL QUARTER CRANK BLOWING ENGINE, 42-IN. STEAM, 84 AIR X 60 STROKE

This can, in my judgment, mean in the long run only one thing, high maintenance and repair cost, which, coupled to the high first cost of this type of engine with the consequent high fixed charges, all tend to make this an undesirable type from the technical, operating and financial points of view.

### THE HORIZONTAL VERTICAL

The horizontal vertical, shown in Fig. 22, presents almost the same conditions, though these are offset by the fact that the running balance of these engines, if properly made, is excellent, and, therefore, their steadiness on their foundations very great. On the other hand, the horizontal vertical requires as much height and much greater foundation than the quarter crank vertical.

Many years ago the late P. L. Weimer, realizing that the energy of the steam was mainly developed in the early part of the stroke, and absorbed by the air mainly in the latter part of its stroke, built what are now known as horizontal vertical engines, with horizontal steam cylinders and vertical air cylinders, both working on the same crank pin. With this arrangement the earlier part of the steam stroke obviously takes place during the latter part of the air stroke. Consequently, a certain equalization of the work absorbed and expended from instant to instant is made, which justified in part the use of this type when speeds were low and inertia effects negligible.

In later years these engines have been built by other builders in very large sizes, and are favorably considered by some operators, although the inertia effect with moderate speeds makes this design wholly unnecessary. In these engines, also, it is obvious that the total work generated in the steam cylinder must be transmitted to the crank pin with a friction loss of some 10 per cent. and then transmitted back from the crank pin through another set of running parts to the air cylinder. It is reasonable to assume that here also there is a loss in friction of 10 per cent., making the mechanical efficiency of this engine, also as a whole, only about 81 per cent.

I have unfortunately no figures giving the mechanical efficiency of these engines in service, but there is no reason to expect that it is much higher than the figure given. On the other hand, with the direct connected steam and air pistons of the horizontal tandem and a proper proportioning of the cylinder diameters, speed, etc., it is obvious that only about 20 or 25 per cent. of the total energy need be transmitted through the running parts, and that the friction of the engine accordingly should be only 6 or 7 per cent. instead of 19, as in the other case.

In confirmation of this, which may seem an extreme statement, tests have been made of Nordberg compressors designed to make use of this principle, which had a mechanical efficiency of 95 per cent. at full load.

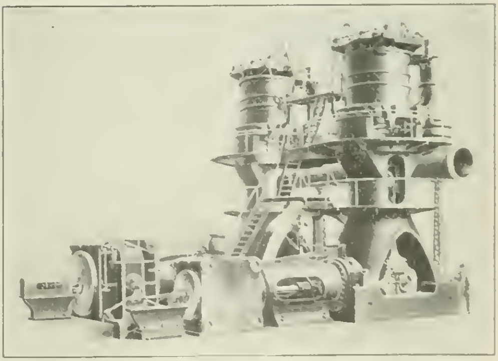

FIG. 22.—HORIZONTAL VERTICAL CROSS-COMPOUND, 52-IN. AND 90-IN STEAM, 90-IN. AND 90-IN. AIR X 60 STROKE BLOWING ENGINE CO., THE WM. TOD CO.

There is, however, one feature of the horizontal vertical engine which deserves attention. It is evident from what we have said above that the inertia of the reciprocating parts can be utilized to reduce the stresses in the running parts very greatly. Nevertheless the inertia stresses due to these heavy parts which move at high velocities alternately in opposite directions exist in the machine as a whole and tend to shift it back and forth on its foundation in the case of the horizontal engine without counterweight, or to pull the crank shaft up and down with an equal force if full counterweight be used, these conditions being reversed in the case of the vertical engine. But when two sets of reciprocating parts at right angles work on the same crank, the inertia effect of one set in horizontal and that of the other in vertical, these components are combined into a single constant stress in a direction exactly opposite to that of the crank, so that by counterweighting completely one set of the reciprocating parts, the horizontal-vertical engine runs in almost perfect balance.

Where foundations are bad and engines must be set upon piles driven through mud to the bedrock these considerations are of much importance, and this type of engine is the best adapted of any to prevent serious shaking of the engine and its foundation or even the whole surrounding country for a distance of many hundred feet, as has happened at one large plant where the blowing engines were supported on piles.

### THE LONG CROSS-HEAD TYPE

This engine requires small foundation and small space for a unit of given size, the vertical height required being about the same as that of any other type of engine with reciprocating parts in the vertical plane except the vertical tandem, or steeple type, which is much higher. The stresses are, of course, transmitted with great directness in these engines from one piston to the other, and through rigid parts, but there is a prejudice on the part of some engine builders against running these engines at a speed which would bring the inertia effect of their reciprocating parts up to the best point for smooth running and low wear. The exact reason for this disinclination I have never been able to discover, and it is only fair to state that it does not hold with all builders, some of whom build engines of this type to run up to seventy or seventy-five revolutions.

There is no doubt that when run at proper speeds and when built sufficiently strong to withstand vibration, this is a useful, reasonably inexpensive and satisfactory type of engine, capable of giving reliable service for long periods at a stretch, such as are needed in blast-furnace work.

It is, of course, open to the objection which exists with all vertical engines, that supervision, inspection and repairs are much more difficult and expensive than they are with horizontal ones.

### THE STEEPLE TYPE OR VERTICAL TANDEM CROSS-COMPOUND

A design of this type of engine built by the Southwark Machine Company is shown in Fig. 23, while nearly all of the prominent builders build this type of engine on demand, the design of valve gear, etc., being different with the different builders, but the general type of construction being the same.

The great objection to this type of engine is its great height with the consequent difficulty of securing adequate inspection and care, and its liability to vibration owing to its height and the elasticity of its small base. It will be seen in the illustration that there are four platforms above the main floor, all of which must be frequently visited for adequate inspection and care of the engine.

It is not to be denied either that these engines are exceedingly difficult of repair. Even where a crane is available, as it should always be in a modern blowing-engine house, there are many parts which it is impossible to reach with the crane without great difficulty, so that this virtually involves partly dismounting the engine for certain repairs. With the limited room available for this work on the platforms it can only be done at a disadvantage, and as a consequence repairs on engines of this type are more difficult, slower, and more expensive than they are on a horizontal engine of the same size.

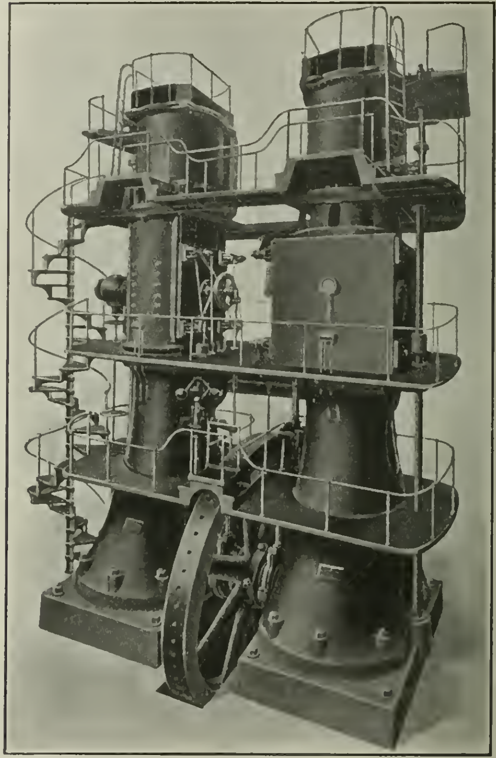

FIG. 23.—SOUTHWARK STEEPLE BLOWING ENGINE QUARTER CRANK COMPOUND

In regard to speed, the engine stands on a relatively small foundation and with its great height excessive vibration is likely to be set up even at very moderate speeds, and this type of engine therefore cannot in general obtain those advantages of high speed which are available to some other types, with consequent loss of

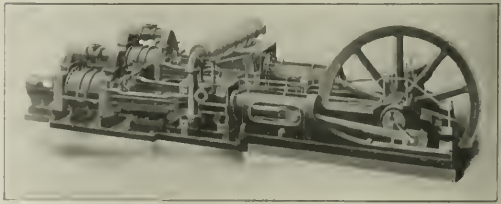

FIG. 24.—HORIZONTAL CROSS-COMPOUND BLOWING ENGINE, 44 AND 84 STEAM, 90-IN. AND 90-IN. AIR X 72 STROKE. THE WM. TOD CO., YOUNGSTOWN, OHIO.

efficiency from not having the most desirable resultant diagram of steam, air, and inertia pressures.

### THE HORIZONTAL CROSS-COMPOUND WITH TANDEM AIR CYLINDERS

This type of engine, shown by Figs. 24 and 25, is open to the disadvantage that it requires the largest and most expensive foundation of any steam blowing engine, and that it requires also a great area of building and ground, leading to high cost on this account, but the building cost as a whole is not so excessive as might be expected because of the very moderate height required with this engine, so that only a relatively low building is needed for its accommodation.

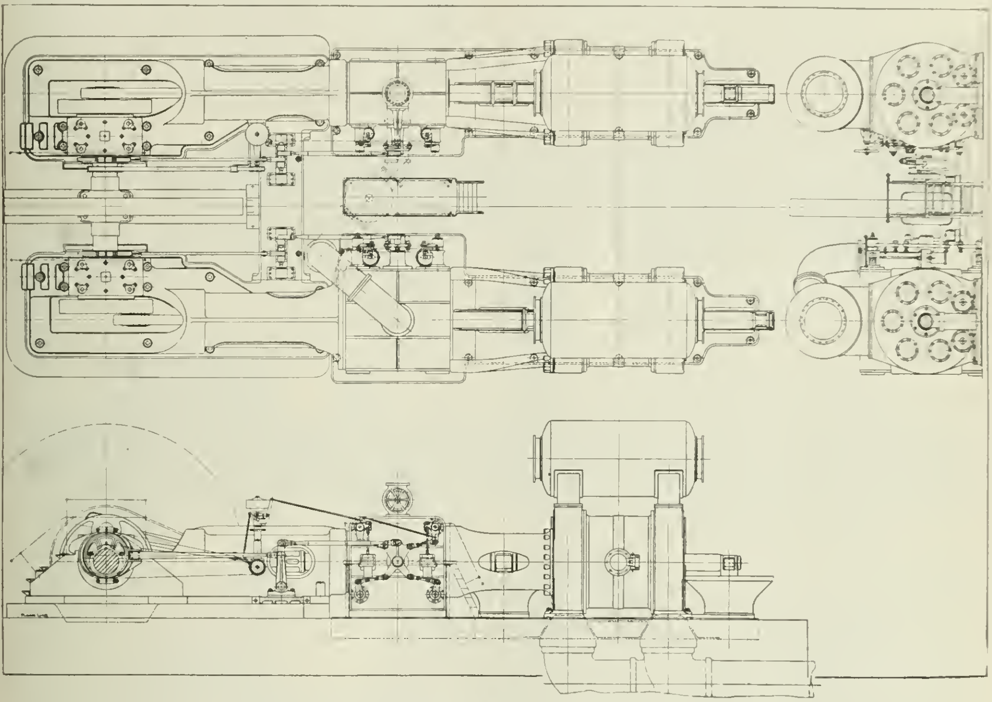

FIG. 25.—"MESTA" CROSS-COMPOUND STEAM BLOWING ENGINE

Its great foundation also acts as a great anvil to absorb inertia stresses and unbalanced centrifugal effects of counterbalance, which tend to cut down to a minimum the possible vibration of the unit as a whole.

Owing to these considerations the engine is capable of being run at the speed best adapted to produce the highest economy and this higher speed of unit permissible as compared with most other types of engines goes far to offset any disadvantages in total first cost under which a unit of a given size of this type labors as compared with that of some other types. The whole of the engine is down on or near the ground level, and I believe that operators who have had experience will bear me out in saying that one attendant will look after two engines of this type more effectively than two attendants can after one of the steeple type of the same size.

This engine has, of course, the desirable feature of transmitting the stress from one cylinder to another through rigid members and not through moving joints, and in consequence it is capable of realizing the benefits of this system to the maximum.

Through the kindness of Mr. E. T. Child, of the Southwark Machine Company, I am able to reproduce in Fig. 26 a set of steam and air cards, one of a large number of sets taken by him personally from an engine of this type, running at a proper speed, in which the efficiency for the average of the whole set was about 91 or 92 per cent. This was in actual operation, no particular attempt being made to obtain a record, and I have no doubt that other well-designed engines of this type would do as well, if run at the proper speed.

One of the essential features in the design of the modern horizontal cross-compounds is the means for relieving the bottom of the cylinders of the drag of the heavy pistons necessary in large units. This is accomplished by putting a cross-head and slide at each end of each of these large cylinders and making the piston

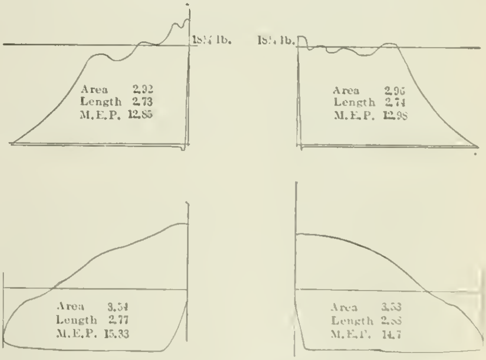

FIG. 26—MECHANICAL EFFICIENCY 92 PER CENT

rods strong enough to carry the pistons clear of the cylinder, so that nothing but the packing ring touches the wall of the cylinder.

In some cases the piston rods are made of high-grade steel and cambered upward before use to the amount by which the weight of the piston will deflect them so that they are perfectly straight in service.

Mr. Nordberg has gone still further and uses a hollow cast-iron trunk of large diameter whose only function is to carry the weight of the piston and take compression stresses, the tension stresses all being taken by a much smaller steel rod through the center.

The type shown is built as a cross-compound steam engine and this type of construction is also much used in gas engines. It has many of the advantages of the horizontal tandem engines but the simplicity and accessibility of the running gear due to the stretcher rods from one cross-head to the other are not so great as in the straight tandem type, and I have never known what advantages this engine possessed to offset these disadvantages unless it be the accessibility of the cylinders due to the elimination of the tandem arrangement. It is a type of engine approved by engine builders very generally, and is recommended by them for high speeds.

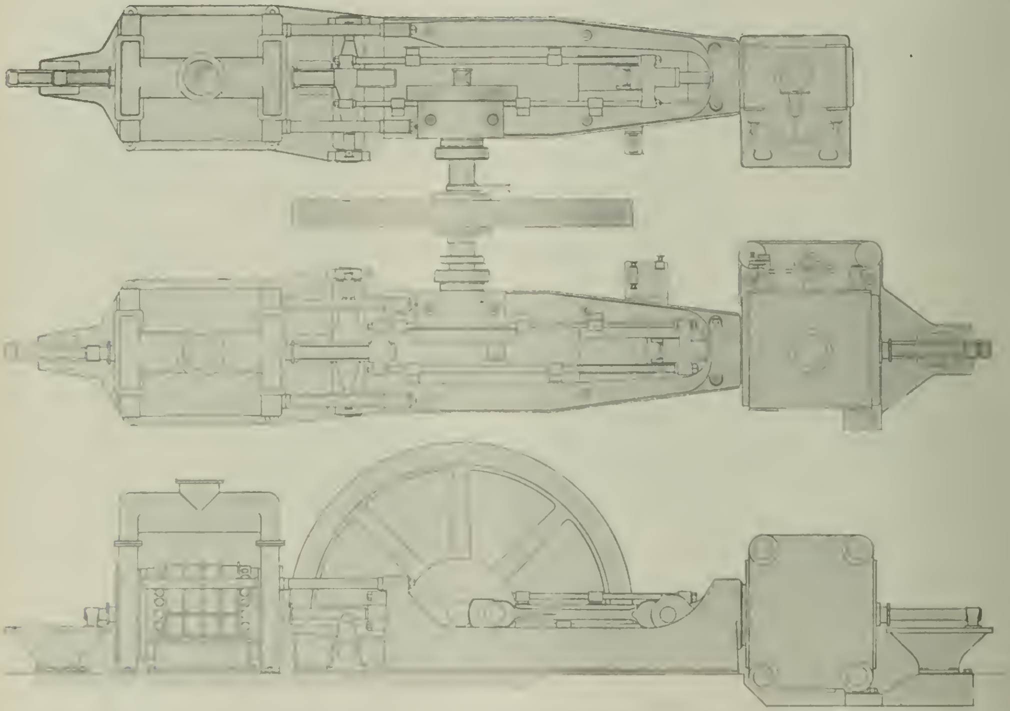

FIG. 27—INSIDE-CRANK BLOWING ENGINE SLICK AIR CYLINDERS 36 IN. AND 72 IN. X 54 IN. STEAM, 72 IN. AND 72 IN. X 54 IN. AIR. ALLIS-CHALMERS COMPANY

This design not only frees the engine from a very heavy friction load, but also relieves the cylinders from wear and puts them on a parity in that respect with vertical cylinders.

### THE INSIDE-CRANK ENGINE

The inside-crank type of engine is shown in Fig. 27.

The crankshaft lies between the two cylinders and the piston rod instead of passing directly from one cylinder to the other; is divided into two parallel rods symmetrically placed with reference to the axis of the cylinders, and in a plane about 45 deg. from the horizontal.

These two parallel rods take hold of suitable projections which are provided on the cross-heads for each cylinder.

This arrangement makes an uninterrupted open space in the axis of the engine and between the two cylinders in this uninterrupted open space the connecting rod and crank work.

The **Foxboro Company**, recently organized under the laws of the Commonwealth of Massachusetts, has taken over all assets and liabilities of The Industrial Instrument Company of Connecticut, which was a holding company, and of The Standard Gauge Manufacturing Company of Connecticut, with factory at Foxboro, Massachusetts. The Foxboro Company manufactures the rapidly growing line of Foxboro improved recording gauges, thermometers, tachometers and pyrometers which are sold by the Industrial Instrument Company having main office at Foxboro, with branch offices at New York, Chicago, St. Louis, San Francisco, and Birmingham. The Foxboro Company owns all of the capital stock of The Industrial Instrument Company. Mr. Edgar H. Bristol and Mr. Bennet B. Bristol continue as president and treasurer respectively of The Foxboro Company. In fact, there are no changes in the personnel or policies of the companies, the above changes being made to concentrate and simplify the organization.

# Concentration of Complex Sulphide Ore from the Mary Murphy Mine[1]

BY GEORGE E. COLLINS

Nothing can be farther from the truth than the common idea that a scheme of ore-treatment can be finally worked out in all its details prior to construction of a milling plant; or that such a scheme, once fixed, should need no reconsideration during the life of the mine it has to serve. This presupposes a homogeneous ore-deposit, unchanged scale and methods of working, and an amount of time and completeness of facilities for testing which are rarely available in practice.

In actual experience, uniform ore-bodies are uncommon. Perhaps the large low-grade dissemination and replacement ore-bodies approach nearest to uniformity; and even these appear so, largely because they are worked on so great a scale that their mineralogical and physical differences are averaged. And while, in the case of some of these large low-grade mines, great sums were spent in testing and on experimental plants before the serious work of construction was commenced, nothing is more certain than that radical changes are yet possible. It is therefore no reflection on the skill of the metallurgist or the thoroughness of his preliminary work, if he finds it necessary to continue testing throughout the life of the plant.

Constant testing is necessary, not merely to indicate ways in which the metallurgical saving of a plant may be improved, but also to control the working costs, and the relation of metallurgical to commercial saving. Furthermore, when the most suitable practice has been established, it is necessary to repeat similar tests at intervals, so as to ensure that no changed factor has crept into the practice, unknown to the management. Even apart from all these, there is a duty incumbent on every engineer to investigate the reasons for what he is doing and the results achieved by it; and last of all, the possibility that by constant study and record of his own results he may add to the general stock of knowledge, by the aid of which he may assist his fellows in solving similar problems more expeditiously.

### Discordant Results Obtained in Testing

I do not know whether engineers experience as much difficulty as I do in obtaining concordant results from their testing work. If so, they do not mention it in their published results. Having had the painful privilege in some cases of "cleaning up" after some of my confrères, I incline to suspect that the difference is sometimes one of puzzling out the discordant results on the one hand, and covering them up on the other.

There are innumerable chances for results to go wrong, either in the preparation of the samples, or in the assay office itself. I suppose that by the exercise of infinite care such discrepancies might be avoided, but so far I have not found any way of discovering or educating infallible men. Both from the point of view of general efficiency of staff and that of effective control of operation, I prefer to get a large amount of work through, and a large number of screen analyses and other tests made, even at the risk of having some inconsistent results included in the reports. Even with this, the tendency is to delay the completion of tests until they have become old history, and have to a large extent lost their value for the guidance of everyday operation.

I suppose everybody has had much the same experience; but it may be worth while, in order to illustrate the difficulties that crop up in this class of work, to give one example:

TABLE I—SCREEN ANALYSIS

Here it will be observed that in the process of crushing, according to the screen analyses, the gold has been raised from 0.48 oz. to 0.92 oz. per ton, and the lead has dropped from 15.25 per cent. to 9.14 per cent.

There is nothing exceptional about the former; we have found that gold tends to accumulate in tube-mills, jig-beds, elevator sumps, etc.—in fact, everywhere in the plant where there is any opportunity for extreme classification to take place, and for exceptionally heavy particles to lodge. I shall return to this subject later.

The changes in the lead percentage are less to be expected *a priori*. But it illustrates the fact that the Hardinge mill (or other tube-mill) is a natural classifier, in which the heavier particles are retained longer, and ground finer, than the relatively lighter particles. As in this plant we always run a machine two shifts or more after making any change before taking samples, this should not lead to discordant results, if the feed were uniform. Uniformity of feed, however, is a most difficult thing to secure, when you have a mine yielding excessively variable ores, and a mill of moderate or small capacity. In this case we have a storage, with some natural mixing in the crushed-ore bins, of over five days' mill capacity; or an average of say two and one-half days' ore always on hand; yet uniformity of feed is an ideal which we have never attained.

Any change in grade or fineness, occurring within a couple of hours of the time when a test is being made, takes several hours before the discharge and feed are equalized; and meantime other changes may have occurred. In order to obtain concordant results from feed and discharge, therefore, it is desirable to continue a test for a week or more, samples of feed and discharge being taken at regular intervals throughout. As we cannot always wait so long for results or tie up a machine so long for purely experimental purposes, it is sometimes necessary to put up with results which we know beforehand may be incorrect, in some direction.

---

[1] Excerpt from the author's presidential address before the Colorado Scientific Society, entitled "Systematic Testing in the Evolution of Mill Practice." The portion here given has reference to the Mary Murphy mill, and affords interesting supplementary data to a descriptive article on the same mill, published in our issue for January, 1914, and to Mr. Dyke V. Keedy's discussion of that article in our issue for March, 1914.

The variations in assay serve as an index to probable corresponding variations in sizing. The sulphide minerals being so much softer than the gangue, it is certain that if there are unequal proportions of mineral in the feed and discharge, there will be corresponding variations in the proportions in the sizing, apart from those normally due to the work performed in the mill.

A similar discrepancy was observed in assays of feed and discharge from a 4-foot Hardinge mill which we used experimentally for regrinding coarse sand tailing, with a view to its treatment on carpets and plates. This operation yielded a small quantity of amalgam, and some carpet washings assaying 2.75 ounces of gold per ton. Yet, during a period of several weeks, the daily samples of heads and tails showed, with I believe only two exceptions, a slightly higher gold content in the latter than in the former. The explanation, in this instance, must be that minute particles of gold and amalgam had lodged in the interstices of the silex lining, and collected in the enriched sands left in the mill before the test commenced, and gradually worked their way out in admixture with the pulp. Had we foreseen this difficulty, we might have avoided it by deferring this test until the mill had been newly lined, and then started it up with a new load of pebbles. We, however, supposed, not unnaturally, that as we intended continuing this test for a considerable period of time, any irregularities of the kind indicated would naturally adjust themselves after running a day or two.

### Conical and Cylindrical Tube Mills

It follows from the foregoing, I think, that no crushing appliance in which, as in the Hardinge and ordinary cylindrical tube-mill, classification takes place, can ever be a perfect non-sliming fine grinder.

The conical end of the Hardinge mill acts, to some extent, as a device to expedite continuous discharge, in much the same way as the device recently brought out by Chalmers and Williams for improving the discharge from a cylindrical tube-mill. The latter, which consists of a perforated diaphragm, between which and the discharge end is a series of adjustable shelves intended to raise the pulp to the center where it can flow out, may be more effective, but has not yet been tried out sufficiently to prove its value. The conical end of the Hardinge, while of limited efficiency, is simple and positive, and really works. One can obtain nearly as small a proportion of slime in a long tube-mill as in a Hardinge, by crowding the feed and using a large quantity of water; but apparently there is then a slight tendency for the discharge to contain still more oversize.

Mr. Hardinge's original contention that with his mill the weight of blow is automatically adjusted to suit the progressively finer particles of pulp as they pass from head to discharge end, and that owing to this automatic adjustment there is practically no necessity for return of oversize, is, according to our experience, not borne out by the facts. As in the case of the tube-mill, if you crowd the tonnage and increase the water sufficiently to obtain a granular product you have to arrange for the return of a very considerable amount of oversize.

In various publications Hardinge has illustrated this supposed zonal action in his mill by cuts in which he superimposes on a picture of the conical mill, an outline of several gravity stamps, commencing with one of heavy weight and high drop, and progressively lessening to one of small weight and low drop at the end; the stamps being supposed to represent the force of blow struck by the pebbles in the corresponding stages of the Hardinge mill as you pass from feed to discharge end.

This is, however, largely a fallacy. It is true that the size of pebbles is automatically graded, to some extent, and obviously the force of blow struck would be thereby lessened. But the peripheral speed is at the same time lessened to such a degree that near the discharge end the pebbles merely slide on one another without cascading, so that there is no crushing action worth mentioning, and what actually occurs is a slight process of abrasion, which is just what we want to avoid. In fact, in comparing the work of the Hardinge with that of the tube-mill, according to our experience, it is pretty much a question of relative first cost and operating expense. We have at Romley one 3½-foot by 16-foot Gates tube-mill, two 6-foot by 22-inch Hardinge mills, and one 4-foot by 22-inch Hardinge. We find that the capacity of the tube-mill and that of one 6-foot Hardinge, using the same feed, are almost identical; and the cost of the Hardinge was about 20 per cent. greater. As to power consumption, we have no means of measuring. The Hardinge uses more pebbles, and has to be relined oftener.

### Separate Regrinding of Sand Tailing and Mineralized Middling

In the Mary Murphy mill, we have hitherto used the 6-foot Hardinges and the tube-mill to do the same work on the same feed. As the result of our experiments, we expect hereafter to do the bulk of the regrinding with the Hardinges, using the tube-mill to regrind the coarse sands from the tables. The 4-foot Hardinge was intended, and is still used, to grind the heavily mineralized middling from jigs, the idea being that this material required for proper granulation a lighter pebble and less total weight of pebbles; furthermore, that it should be more satisfactorily ground by itself, unmixed with the particles of hard, tough quartz and rhodonite of the gangue. I now doubt very much if this latter hypothesis was correct; and incline to suspect that one effect of the hard gangue particles may be to protect the soft grains of mineral, in some degree, from sliming after they have once been crushed fine enough. What, however, is certain is that crushing the jig-middling in a separate machine enables us to realize precisely what result we are actually obtaining. This is indicated by the color of the discharge, which looks a good deal like ink, and by the screen analyses, which show anywhere from 30 to 70 per cent. of —200 size, averaging in metallic contents 65 per cent. of the lead and 51 per cent. of the total zinc.

The sizes below 100-mesh contain nearly all the lead and most of the zinc in the feed (93 per cent. of the total lead and 85 per cent. of the total zinc).

As stated above, by greatly crowding the feed we are able to lessen the proportion of unduly ground material, to a very large extent. This is well shown by the screen analysis (Table II) which shows only 12.1 per cent. of —200-mesh material.

The use of this method is, however, not always possible; for in a small plant, or even one of moderate size, the tonnage available of any given material is limited, and is fixed by the relation between various factors due to other machines; and by no means always corresponds with the sizes of machines commercially manufactured. And this again is a decided disadvantage, for small plants, of the entire tube-mill class of machine, in which the character of the product as well as the cost of operation is modified by the quantity of feed.

Moreover, in the example shown, the lessened quantity of undersize is obtained at the expense of producing a prohibitive proportion of oversize (49.3 per cent.).

To show the enormous influence on product of differing quantities of feed, the character remaining similar, I reproduce screen analysis (Table III) which shows that by reducing the feed to 14 tons, keeping the other factors approximately constant, the result was entire elimination of oversize, but the increase of —200-mesh product to the enormous figure of 72.8 per cent.

TABLE II—SCREEN ANALYSIS

4 Ft. Hardinge Mill. Re-Grinding Jig Middling

Screen analysis (2) also illustrates in a rather striking way the tendency for the total gold in discharge to exceed that in the feed. There were 11 screen sizes in each case, and in all but one size, when feed and discharge ran about the same, the gold was far higher in the discharge. The average gold indicated by the assays in the feed was 0.15 ounce, and in the discharge 0.44 ounce. Substituting for the highest assay in the discharge the average of the assays on the adjacent sizes, the average of the discharge is reduced to 0.37 ounce, or two and one-half times the average of the feed.

We are now installing a pair of rolls, to be set close, to recrush these soft middlings, and shall hold the 4-foot Hardinge in reserve, for use when some of the other machines are out of commission for repairs.

### Value of Screen Analyses

I have always been disinclined to attach overmuch weight to the details of screen analyses, excepting as to their general trend. If we take two identical samples, and compare duplicate screen analyses on them, made by different individuals, or even by the same person, we usually find wide variations in the results. Such differences indeed we may expect, in view of the rectangular apertures employed, and the varied forms of the particles to be screened. When a particle is, in every section but one, larger than the screen aperture, and in that one section just small enough to pass through the aperture, but only if rightly oriented, it is clear that particle and aperture may be brought into contact perhaps a hundred times before it will pass, and in the meantime sharp edges of many other particles, which at first would not have passed through, may have become worn down sufficiently to enable them to pass.

The difference between screen analyses performed wet and dry is well known.

Some of the spotty gold assays which have crept into our screen analyses may perhaps be due to the alternate use, for such tests, on rich and poor material, of the same nests of screens. In the finer sizes, a considerable proportion of the apertures becomes blinded, and if there are small particles of gold included in the material thus held in the screen, they may become dislodged when screening subsequent samples, so introducing erratic assays into the latter. As far as possible, however, we guard against this contingency by using a different set of testing screens for high-grade and low-grade mill work.

I referred above to occurrences of free coarse gold in the mill. So far as I can learn, during the entire 30 years of the mine's history, no specimen showing free gold has ever been seen. Yet the existence of pockets of free gold has been inferred from the occasional erratic bunches of extremely rich ore encountered, and the unusually spotty assays, which suggested that the rich ore could not exist in the form of telluride or other friable material.

At intervals, in the mill, we have found sudden evidences of coarse gold. The gold ordinarily caught on the plates is fine; by dissolving the amalgam with nitric acid, 82 per cent. was found to pass a 100-mesh screen. Its fineness, moreover, averages only 550. The other kind of gold is of about 650 fineness, and coarse—nearly all of it over 20-mesh. It is mostly caught on the carpets used below the plates, and on the first few riffles of the Card tables which are fed from the two first spigots of the classified line. Both these products are taken direct in pipes to a grinding pan of arastra type, with a bottom paved with silex bricks, and a stone drag, where they are ground continuously with quicksilver; the amalgam being cleaned out daily through a spout in the bottom, and the overflow settled and added to the high-grade concentrate. In this way we avoid difficulty in sampling and selling unnecessarily spotty concentrates, and furthermore are able to keep slightly better control of the gold contents throughout the system.

At times on the jig-beds, we have been able to sort out quite a number of pounds of metallic particles, attached sometimes to quartz and sulphide minerals.

These range in size from 2 mm.—the mesh of the jig-screens used—up to 1/3 inch. One or two such nuggets have been found in the trommels over ½ inch in diameter, nearly all of gold of about 670 fineness.

### Methods of Calculating Recovery

There has been a great deal of discussion in the technical press during the past year with reference to methods of calculating rates of extraction in mill work. We have the partisans of the method of calculating from weights and assays of tailing, or from assays entirely, excluding weights, together with products, on one hand, and on the other hand, those who insist on the necessity for sampling heads, which usually requires a sampling plant. To me it seems a question to be decided on the merits of each individual case. Poor samples of mill feed are worth very little; and accurate sampling usually adds materially to costs of construction and operation. Samples of tailing can usually be obtained with relative accuracy; and products must be accurately sampled for purposes of sale, so that their accurate determination is chargeable, not to cost of mill operation, but to cost of realizing products. Where only one or two products are to be marketed, it seems to me that the method of calculating heads is admissible; the objection to its use comes with more validity from the general management, which may require the independent check on the mine work which is afforded by actual sampling of the mill heads.

Where on the other hand we have many metals to be recovered, and many products to be made, which are marketed at irregular intervals, samples of headings become almost indispensable in order to control the daily work. Even with this help, in the case of the plant which I have in mind, the locked-up material in sumps, mills, etc., so affects the daily tailings that (especially as to gold content) it does not always correspond with the daily feed. This is strikingly illustrated by the fact that, when we have a daily feed which happens to run up in gold, the tailing often shows no increase; but it does so for several days thereafter.

In the course of the discussion above referred to, Mr. W. S. Welton objected to the use of tailing assays in figuring savings, for the reason that the water decanted from the tailing sample "invariably contains higher values than the material which settles and accordingly carries away a large percentage in suspension." To quote from his article in the *Engineering and Mining Journal* of July 12, 1913: "Under working conditions, it is impossible to ascertain directly the real value of the tailing.

"From the moment concentration commences, the water made use of carries off mineral of value, and this continues all through the process. The amount of floating mineral will vary with the fineness of division of the particles, degree of concentration, amount of water used, and inclination of the tables, or with the rapidity of concentration. The effect of these circumstances is to cause the settled tailing to be invariably of lower assay value than if there was no float."

A little further on Mr. Welton states that "to estimate the extraction" it is "clearly necessary to know either the correct value of the mill feed or of the tailing," and in view of the difficulty he considers to exist in sampling the tailing recommends dependence on sampling the feed.

This contention was supported by a number of assays taken in the course of some concentration tests on silver ores. It would, however, be difficult to find a more striking case of the fallacies which may result when one argues from the particular case to the general. In the first place, while the suspended slime tailing from concentration is usually of higher assay than the sand, it is not "invariably" or necessarily so—in my own experience I have found several instances where the contrary was true. In the second place, if proper time is allowed for settling, and lime or other aid to settling made use of, the loss in suspension is usually small. Finally, as the ease of taking correct samples increases with the fineness of the particles, there is no excuse for not getting accurate samples of the water, plus whatever matter it may hold in suspension; nor is there any insuperable difficulty in evaporating the entire sample to dryness, water and all. What we do in practice is to settle the sample with lime, decant the clear water, and evaporate the rest to dryness. But as a further precaution, we occasionally save the whole of the water decanted, evaporate it and assay the residue. In the case of the Mary Murphy, this is much richer than the sand tailings; but the proportion of solids is so small that it makes little difference.

The last time this test was made the proportion of solids in the decanted water was 0.25 per cent., which assayed:

Gold, trace; silver, 1.4 ounces; lead, 4 per cent.; zinc, 18.7 per cent.

The weight of water is about fifteen times that of the dry pulp, so that it is easily seen that the loss suspended in the water is negligible. I think every mill should make such tests at intervals, in order to guard against a peculiarly insidious form of loss; but in my experience it is rarely the case that the inaccuracy in tailing samples caused thereby is of any moment, assuming that the tailing is properly settled.

There are three essentially different ways in which to calculate mill savings: from head and tailing, from head and products, and from products and tailing. In simple mills, recovering but one or two kinds of product, it is a good plan to calculate the saving in all of these three ways, and compare the results. This is an excellent way of testing the accuracy of the sampling all through; and personally, although my own experience has generally been that I was quite unable to obtain the same result with the different methods, yet I have always thought it a very admirable plan. Nothing else calls your attention so forcibly and at the same time so promptly to the weak points of your sampling work. Even with the most complicated mill systems, it is well to take stock in this way at intervals.

Where owing to expense or other reasons only part of the sampling can be done automatically, it is clear that the tailing should be selected for this; because, after all, what primarily concerns the mill man is what he is losing, and how far it will pay him to follow it. The products are less essential to watch, because the cash account directs attention to them in the most forcible way possible; and also because the methods of sale usually ensure systematic sampling and record, even without conscious attention on the part of the operator.

It is frequently forgotten that to calculate the percentage of saving is, in itself, of no value. What we really want to know is, what is contained in the material that we are losing, and to what extent is it worth while to pursue it farther. If we are throwing away $10 per ton from a $40 ore, we are obviously losing what, under most conditions, it will pay to save. If we are losing $1 from $4 ore, it will rarely pay to attempt to recover it. Yet the percentage of saving is the same in each case.

---

**Peruvian copper production** for 1913 amounted to 27,940 metric tons, or say 27,500 English tons, an increase of 100 English tons over 1912. The output in metric tons was made up as follows: Bars, 20,340; matte, 4462; shipping ores, 3138.

# Soot-Fall Study of Pittsburgh

BY JOHN O'CONNOR, JR.

In two interesting papers contributed to your journal by John B. C. Kershaw,[1] mention was made of the fact that a study of the soot-fall of Pittsburgh had been carried on in connection with the "Smoke Investigation" of the Mellon Institute, University of Pittsburgh.

The study was made by Dr. R. C. Benner, the Chemist of the Investigation. Dr. Benner was assisted by George Edward Bost. The study began in April, 1912, and extended over a period of a year. Twelve stations were selected in different parts of the city and samples of the soot-fall were secured by exposing jars on the roofs of buildings. Glass jars about 4″ x 10″ were used in summer, and copper cans, tinned inside, in the winter.

The jars were exposed for a month at a time. When a jar was brought to the laboratory, a 100 c.c. sample of the water was taken and tested for acidity with methyl-orange. If acid were found to be present, it was titrated with standard $Na_2CO_3$. The total volume of the monthly sample was determined and the total acid calculated. The month's sample was then evaporated and weighed in a porcelain dish, placed on the water bath, heated in the steam oven about 18 hours, dried in a dessicator and weighed. 1.0000 Gram of the year's dried sample from each station (of stations 2, 4 and 5, 2.0000 Grams each), was wrapped securely in a quantitative filter paper and extracted with ether in the Soxhlet extractor to determine the tar content. The extracted soot was ashed and weighed and the iron in the ash was determined by standard potassium permanganate. Table 1 shows the monthly soot-fall in grams at the different stations. The total soot-fall in grams for each station is also given and below the table is the calculated soot-fall in tons per square inch per year (See Map).

Table III shows the calculated amount in tons at each station, of tar, fixed carbon, ash and iron.

TABLE III.
SOOT-FALL IN TONS PER SQUARE MILE PER YEAR

| Sta. No. | Composition of Soot<br>Tar<br>Tons | Fixed carbon<br>Tons | Ash<br>Tons | $Fe_2O_3$<br>Tons | Total<br><br>Tons |
|---|---|---|---|---|---|
| 1 | 13 | 131 | 306 | 145 | 595 |
| 2 | 16 | 713 | 809 | 412 | 1,950 |
| 3 | 10 | 202 | 189 | 269 | 670 |
| 4 | 19 | 417 | 844 | 380 | 1,660 |
| 5 | 21 | 357 | 704 | 548 | 1,630 |
| 6 | 4 | 322 | 343 | 309 | 978 |
| 7 | 8 | 300 | 309 | 195 | 812 |
| 8 | 7 | 286 | 419 | 210 | 922 |
| 9 | 5 | 211 | 344 | 188 | 748 |
| 10 | 3 | 274 | 336 | 108 | 721 |
| 11 | 8 | 391 | 378 | 218 | 995 |
| 12 | 7 | 200 | 333 | 153 | 693 |

It is unfortunate that these figures cannot be compared with those obtained elsewhere, as, for instance, in London, Leeds, and Glasgow, because the method used in each place was different. Mr. Kershaw's plea for the adoption of a uniform system as that suggested by the committee named at the "International Smoke Abatement Exhibition and Conference," held in London, in March, 1912, becomes apparent at once.

[1] The October jar from station No. 6 was broken, and the weight of the soot-fall for this month was calculated by taking the average monthly soot-fall for the other ten stations during the entire year, combined with the average monthly soot-fall for station No. 6 for 11 months.

[2] The January sample from station No. 9 froze and the jar was broken. The weight of the soot-fall was calculated for the month of January by taking the average monthly soot-fall for the other 10 stations during the entire year, combined with the average monthly soot-fall for station No. 9 for all eleven months.

Table II shows the per cent. analysis of the year's sample for tar, ash, fixed carbon, iron in the ash, and iron in the deposit.

TABLE II—PER CENT ANALYSIS OF YEAR'S SAMPLE OF EACH STATION

| Number of Station | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Tar | 2.19 | 0.82 | 1.56 | 1.12 | 1.26 | 0.36 | 1.00 | 0.74 | 0.62 | 0.42 | 0.76 | 1.04 |
| Ash | 75.84 | 62.60 | 68.30 | 73.77 | 76.82 | 66.68 | 61.94 | 68.20 | 71.16 | 61.42 | 59.96 | 70.14 |
| Fixed carbon | 21.97 | 36.58 | 30.14 | 25.11 | 21.92 | 32.96 | 37.06 | 31.06 | 28.22 | 38.16 | 39.28 | 28.82 |
| $Fe_2O_3$ in ash | 32.08 | 33.73 | 58.78 | 30.98 | 43.66 | 47.44 | 38.44 | 33.38 | 35.42 | 24.05 | 36.52 | 31.47 |
| $Fe_2O_3$ in deposit | 24.30 | 21.10 | 40.10 | 22.90 | 33.60 | 31.60 | 23.80 | 22.80 | 25.20 | 14.80 | 21.90 | 22.10 |

At the Convention of the "International Association for the Prevention of Smoke," held in Pittsburgh, in September, 1913, at the suggestion of Bailie Smith f Glasgow, Scotland, a committee was appointed of which Mr. E. P. Roberts, the Smoke Inspector of Cleveland, was made chairman, to induce cities of the United States to take up the method suggested in England.

---

[1] Methods for investigating and recording atmospheric impurities, including the soot and dust suspended in the atmosphere, June, 1913, Vol. XI, No. 6, p. 339.

Notes on the standard apparatus and method for measuring the amount and character of atmospheric pollution, November, 1913, Vol. XI, No. 11, p. 615.

It is to be hoped, that this committee will be successful in its work and that in the near future cities of the United States will be able to compete by means of a uniform method, in an effort to show a low atmospheric pollution.

## A Successful Method of Amalgamating in Cyanide Solution

BY JOHN RANDALL

In case coarse gold is encountered in the cyanidation of ore, the question of amalgamation is not so important as formerly. When separate treatment of sand and slime was the general practice the question was quite important, but the problem was never satisfactorily solved. With the prevalence of all-sliming the case is quite different. The ore travels in a closed circuit through the fine grinder and classifier until reduced to slime, and any coarse gold which may happen to be in the pulp is thus "worn out" and gives no trouble in the extraction department. Therefore, in all-sliming mills it is considered good practise to simplify the process by cutting out amalgamation, even when the ore contains coarse gold.

However, there are cases in which it is best to treat a part of the ore as sand, and then if it contains coarse gold the question of amalgamation comes up. To crush in water, amalgamate, dewater and then treat with solution occasions a loss of cyanide besides complicating the process; while amalgamating in cyanide solution has its drawbacks. In the latter case we have the gold cleaned and brightened by the cyanide solution and in the very best possible condition for amalgamation, but we are confronted by new difficulties. The solution attacks the plates, rapidly eating them away, while the amalgam is hardened by the dissolution of the mercury until it becomes unmanageable and the plates inefficient. The difficulties encountered have generally been sufficient to result in the abandonment of amalgamation in cyanide solution after many careful and persistent efforts.

It is the object of this article to bring into notice a phase of the subject which seems to have escaped general attention.

It is well known that if metallic sodium be mixed with mercury and immersed in a watery solution the action of the sodium in going into solution as NaOH at the surface of the mercury will produce practically the same result as that occurring at the cathode of an electrolytic cell. If there is gold or other metals in the solution they will be deposited upon the surface of the mercury and amalgamated. But in plate-amalgamation the mercury and sodium is spread out into such an exceedingly thin film that the sodium is rapidly oxidized and carried off, the good effect of it being noticeable for only a very short time after dressing the plates. This is the main reason why amalgamators generally regard sodium as of little or no value.

### Riffles Substituted for Plates

However, if riffles containing mercury be substituted for plates the last named difficulty is overcome, and it is possible to keep the quantity of sodium in the mercury fairly constant. Some time ago the writer was in charge of a mill, treating sand and slime separately, where gold nuggets the size of a pea were sometimes found, although the ore averaged a little below $10 per ton gold. The ore was a weathered dump and contained some copper as azurite, but no native copper. The crushing was done in solution in a Chilean mill through 16-mesh screens. The mill was provided with plates, but they were taken out and riffles were substituted.

In cleaning up it was found that the greater part of the amalgam was so fine that it could be squeezed through chamois leather, and the bullion from the riffles was found to contain about two pounds of copper for each ounce of gold and silver. It is evident that the copper was deposited from the solution, and that in addition to recovering free gold that passed through the screens, the riffles had been of service in mitigating troubles arising from copper in the zinc boxes.

It was aimed to keep the amount of sodium just below the point where the mercury would amalgamate a freshly brightened iron nail. To accomplish this some mercury containing a large amount of sodium amalgam was kept on hand in a dry, glass-stoppered bottle and a determined amount of this put into the riffles every four hours. No mercury was detected in the solution, and as none was floured, a weighing at the end of the run showed no loss except what might be expected in retorting.

### Returning Part of Riffles Discharge by Tailing Wheel

In operating riffles it is found that those of the best design will choke when the feed is temporarily diminished below full capacity, and some trouble is experienced in getting them started again. This trouble may be obviated by placing a small tailing wheel in such a manner that it will return a variable amount of the outflow back to the head of the riffles as shown in Fig. 1. By this means riffles of comparatively large capacity may be operated on a small amount of pulp. A section of the feed spout may be made to slide in telescope style, or a movable partition may be placed in the spout to cut out a variable amount of pulp.

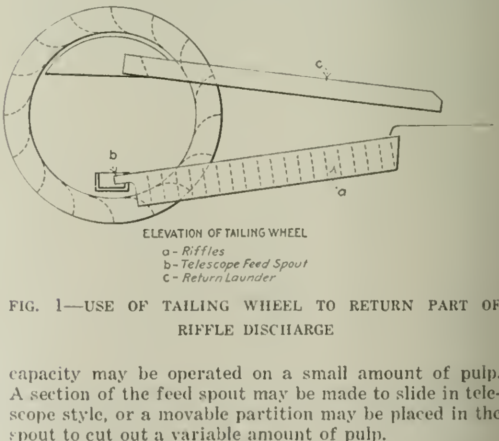

FIG. 1—USE OF TAILING WHEEL TO RETURN PART OF RIFFLE DISCHARGE

I think it very doubtful if it would pay anybody to make riffles should they desire to use them with mercury, for this or any other mill purpose. The Pierce riffles, called the Pierce amalgamator, can be depended upon if given the proper amount of feed, and the sodium will protect the metal parts. They look somewhat expensive in first cost, but any riffles that will hold mercury and not pack with sand are open to the same objection. In operating riffles it is quite necessary to have a screen above them to intercept gravel that may occasionally come from a broken mill screen.

Boulder, Colo.

The Alaska Gold Company expects to have its immense mill ready for operation before the end of this year as planned. Excavations have been completed and erection of steel should commence this month.

# Mechanical Refrigeration—III

## The Absorption Refrigerating Machine

BY H. J. MACINTIRE

The absorption refrigerating machine, although one of the first designs for artificial cooling, has only recently been given the careful attention necessary for economic results, but now its construction has been so perfected as to give it an unassailable place in the refrigerating industry. Yet the operation and details of the cycle are so foreign to common steam-engine practice as to cause considerable trouble to those unfamiliar with it. It is hoped that the following will be so presented as to make the working of the machine seem as perfectly clear and simple as it really is.

Before taking up the design of the absorption machine in detail the few similarities to the compression machine and the notable differences of the two will first be pointed out. The condenser and cooler are identical in both machines. The compression machine uses an anhydrous refrigerant, whereas the absorption machine uses ammonia only—part of the time as a solution in water and the remainder of the time as nearly anhydrous ammonia. The compression machine compresses the vapor by the displacement of the piston driven by a heat engine or electric motor. The absorption machine utilizes the heat in the steam directly to separate the ammonia out of its solution (thereby leaving a weak aqua in the still) and to drive it finally into the condenser where it is condensed by the action of cooling water as in the other type of machine. In order to provide continuity of action the vapor from the cooler must be returned to the still or generator by combining it in solution again with the weak aqua from the generator. The absorption machine has no moving parts except a small pump, and uses the heat energy in the steam. There is, in fact, no reason why atmospheric exhaust steam may not be used to advantage in most cases, provided the absorption machine is designed with the necessary heating surfaces in the generator for this condition of operation.

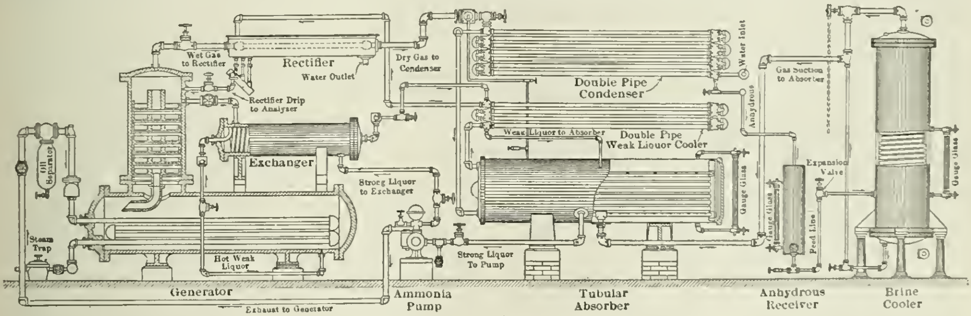

FIG. 1

### THE ABSORPTION CYCLE

Let us refer to Fig. 1 and consider the absorption cycle in detail. The generator is usually a cylindrical shell containing a solution of ammonia, from 30 per cent to 35 per cent in weight, and a number of steam coils connected in front to steam headers. The action of heat tends to dissociate the ammonia from the solution, and the ammonia, as well as some water vapor (under a pressure slightly in excess of the condenser pressure) pass into the upper portions of the generator called the analyzer. In the latter is a counter-current of strong aqua colder than the vapor arising which condenses most of the water vapor and cools the ammonia vapor of some of its superheat, an operation which is nearly completed in the water or air-cooled dehydrator. The analyzer and dehydrator also act as a check to excessive ebullition in the still and tend to prevent the aqua of the generator from boiling into the condenser, which would preclude further refrigeration. Drips from the dehydrator pass by gravity into the generator.

The vapor from the cooler must be returned to the generator in the form of a solution or strong aqua. To do this the weak aqua from the generator is first cooled and then sent into the absorber where it comes into intimate contact with the vapor from the cooler. The pressure in the absorber is but slightly lower than that in the cooler (some 10 lb. to 35 lb. absolute) and the temperature of the weak aqua entering the cooler is from 80 deg. Fahr. to 110 deg. Fahr. The result is that the affinity of the cool weak aqua is quite strong for the ammonia and a stronger aqua results with a liberation of heat which must be removed by cooling water or the temperature will rise and prevent satisfactory operation. The strong aqua, cooled to about 90 deg. Fahr., and at a pressure of one or two atmospheres must be returned to the generator under a pressure of eight or twelve atmospheres. As the weak aqua had to be cooled before admittance to the absorber and the strong aqua requires heating before being pumped into the generator very excellent results are obtained by the use of a counter-flow exchanger—usually of the double-pipe (one pipe within the other) construction. The hot weak aqua then proceeds from the generator, through the exchanger, where it gives up its heat to the strong aqua and then enters the absorber. The heated strong aqua is piped into the upper part of the analyzer, where it flows by gravity into the generator and cools the ascending hot gases being driven off from the generator.

In summing up, the analyzer and the dehydrator provide a means for moderate cooling of the ammonia vapor and nearly perfect separation of the water content. The exchanger increases the efficiency of the plant by saving steam in the generator and cooling water in the absorber. The generator and the absorber are the two important, distinctive absorption features. The condenser and cooler are identical with those used for the compression form of refrigerating machine.

Keeping in mind the general construction of the two principal designs of refrigerating machines and their cycles, it is desirable now to make a brief comparison of them. The compression machine utilizes the expansive force of the steam which does work on a piston, which likewise in turn does work on the refrigerating medium. The steam is usually taken at boiler pressure into the cylinder of the steam engine and is exhausted (except for the larger machines) into the atmosphere or into heating coils at nearly atmospheric pressure. The percentage of heat in the steam converted into useful work is usually not in excess of 10 per cent and often is much less. The absorption machine transfers the heat in the steam to the aqua in the generator. As the steam condenses, the heat given up to the aqua is between 900 and 1000 B.t.u. per pound, and the efficiency of the conversion is approximately 75 per cent.

The greatest point in favor of the absorption machine, speaking economically, is that it may be designed to use exhaust steam, and requires power only for the strong aqua pump and such other auxiliary apparatus as apply to the particular installation—such as brine-circulating and deep-well pumps, fan for the circulation of air, etc., and the exhaust from these (if steam-driven) may be employed in the generator. Also in a properly designed and compact grouping of the separate machines the decrease of the cooler pressure does not offer any difficulties and the cost of a ton of refrigeration (cooling at the rate of 200 B.t.u. per minute) does not increase very much with low refrigerating temperatures. Brine temperatures of — 10 deg. Fahr. or — 20 deg. Fahr. are readily and economically obtained. The absorption machine, however, is more costly as a rule and covers more space than an equally sized compression machine. Considerably more ammonia is required for charging, and the loss due to leaks and disintegration is greater.

As has been stated exhaust steam may be used in the absorption machine, and also that 75 per cent to 80 per cent of the heat in the steam passes into the aqua of the generator. Such being the case, it would seem at first that the absorption machine is by far the most economical of all refrigerating machines and that where exhaust steam was a by-product the compression machine could not possibly be a competitor. Yet, although certain advantages can be claimed for the absorption machine, it does not give in practice the economy of operation that it would seem capable of. According to competitive tests it has been found that about 30 lb. of steam per hour per ton of refrigeration is required for either type of refrigerating machine.

The reason for this lack of good showing on the part of the absorption machine may be seen by considering the analysis of the heat necessary for the operation of the generator per pound of ammonia condensed in the condenser, taken from an actual test.

| | |
|---|---|
| 1. Heat of solution at average concentration of aqua (31.8%) | = — 193.0 |
| 2. Difference in heat of the liquid above saturation (129.7 — 63.7 × 1.154) | = + 77.4 |
| 3. Heat of vaporization at temperature of saturation (from condenser pressure) | = — 518.1 |
| 4. Heat necessary to superheat the vapor (0.52 × [152.0 — 62.7]) | = — 47.5 |
| 5. Heat necessary to heat the strong aqua to the temperature of the outgoing weak aqua (6.65 × 50.1 × 1.018) | — 349.0 |
| Total | — 1030.2 |

This very large total of 1030 B.t.u. per pound of ammonia condensed requires from 26 lb. to 34 lb. of steam per ton of refrigeration per hour, depending on the operating conditions. Items 1, 3 and 4 are inevitable and vary but little with different conditions of operation. Item 5 could be eliminated by supplying the strong aqua to the generator at the temperature of the aqua leaving the generator. As this is impossible without supplying additional heat, the only means of making this item small is to have little aqua in circulation per pound of ammonia condensed, namely, by the use of large differences in the concentrations of the weak and strong aqua. Usually the number of pounds of weak aqua circulated per pound of ammonia condensed is much greater than in the case above (6.65), especially if care is not given to the operation of the machine. However, where exhaust steam is available and cannot be otherwise used, the absorption machine is generally the best refrigerating machine to employ.

# The Igneous Concentration of Metallic Values from Mixed Sulphides—I.

BY F. L. CLERC

In the earlier paper, on the "Igneous Concentration of Zinc Ores,"[1] I directed attention to three well known processes of manufacturing zinc pigments, or of pigments containing zinc, and suggested modifications in certain particulars, to adapt them to the concentration of zinc as a sublimed product.

In reference to my present subject, I made the following statement: "Much is to be expected from pyritic smelting if concentration (of values) at the top of the furnace becomes an object of consideration."

In returning to the subject, it may be well to state clearly at the outset what I shall attempt to do, and what I wish to avoid even the appearance of trying to do.

The igneous concentration of copper in the form of matte, from ores carrying only a few per cent of copper, and the production of metallic copper from these mattes, has had a phenomenal development in the last twenty years, and has established itself in all quarters of the world.

I do not propose to write even an outline history of this development. Nor do I propose to examine into technical details, or to try to explain variations in practice imposed by local conditions.

The idea underlying much of this progress is to utilize, as far as is practicable, the heat evolved by the rapid oxidation of sulphur and the metal with which it is combined, to carry on the smelting operation. The object of metallurgy is to separate a metal from its ores, and in some cases from other metals. Carbonaceous fuel is needed in most igneous processes to supply the heat required; in so far as this heat can be effectively generated by metals and metalloids, less carbon will be required.

## Relation of Pyritic Processes to the Igneous Concentration of Zinc

In applying this principle of the generation of heat by the rapid oxidation of metallic sulphides to the closely related subject of the concentration of zinc by sublimation from mixed sulphides, it is important to know what it has done for copper metallurgy, and to inquire a little into its theory, how it has affected practice, and along what lines it has been developed. There are two classes of metallurgists who are likely to become interested in the igneous concentration of zinc. First: Those copper smelters whose ores carry an appreciable amount of zinc; to them my treatment of the subject may appear superficial and inadequate. The other class are those who have to do with ores of zinc intimately mixed with other sulphides, but who have not had practical experience in copper smelting. These latter may find, by looking into the subject, that they can profitably make use of a source of heat which the copper smelters have quite fully utilized.

I propose then, in a very general review of the subject, to select a few notable events, as a traveler in a strange country marks his course by land marks. I choose as the events by which progress is marked public demonstrations on a commercial scale, which have been adequately reported upon.

The account here given of these demonstrations is taken from the Presidential address of Mr. Robt. C. Sticht read before the Australasian Association for the Advancement of Science, at the Adelaide meeting in January, 1907. By referring the reader to this address for a connected story of the earlier investigations and discoveries, which prepared the way for these experiments, and for a connected account of what has been done since, I can bring my subject within the limits of a single article, and in some measure trace the application of the idea. The demonstrations chosen are: First. The experiments of three Russian metallurgists in Bessemerizing copper matte, the results of which were published in the Russian Mining Gazette of May, 1870, and also in Berg und Hüttenmannische Zeitung in 1871. Second. John Hollway's experiment with copper ores in 1878-9, reported to the Society of Arts February 12th (or 22d?), 1879. Third. The introduction of the process of Bessemerizing copper mattes at the Parrot Works in Montana under the supervision of agents of Manhés. Fourth. The revival of Holloway's process, with modifications adapting it to then prevailing conditions in Montana and Colorado, by W. L. Austin and others. Fifth. The establishment of a great copper industry at Mt. Lyell in Tasmania.

### Definition of Terms. "Pyrite" or "Pyritic?"

Before recounting these events, it is desirable that a clear understanding should be reached as to the meaning of certain terms which must be used. These words are used by different authorities to convey different meanings. Thus we have "pyritic" smelting and "pyrite" smelting, also "pure" and "partial pyritic" smelting, or "pure" and "partial pyrite" smelting, a needless assortment of names, resulting in some confusion of meaning.

It has been urged by some against the adoption of "pyritic" smelting as a generic name to classify a group of allied processes, based on the utilization of the heat evolved by the rapid oxidation of sulphur and metallic bases, by means of an air blast, that this name was appropriated by John Percy for the iron-matting process, long practiced in Europe, in which unroasted iron sulphide was added to the charge for the purpose of collecting the precious metals it contained, in an iron matte. As these metals were extracted from the matte by means of lead, since a cupriferous lead bullion was troublesome to treat, copper was excluded from the charge as far as was practicable. The force of this objection is somewhat weakened by the now recognized fact that the heat of combustion of the iron sulphide was to some extent utilized to carry on the operation. Moreover, this process is not deposed from its proper class as one of the pyritic processes; it still holds its position as one variety of pyritic processes. It is not unusual in scientific classification, where a single species has been the sole representative of a genus, and is given a comprehensive name, to transfer this generic name to a class of similar things discovered later, which have to be classified, and to relagate the first species reported to a subordinate position.

A more serious objection can be made to the name "pyrite" smelting. Pyrite is a name coined to accurately denote a particular mineral, $FeS_2$, and distinguish it from other metallic sulphides occurring as ores, and include in mining and metallurgical parlance in the general term of "pyrites." Used as a noun in connection with smelting, the sense may be altered with the preposition required to correct the ellipsis. It is not the smelting *of* pyrite, nor the smelting *with* pyrite, nor even the smelting *by* pyrite, that conveys the meaning intended. Unless "pyrite" is used adjectively, and deprived of its specific meaning, a whole class of minerals more or less included under the popular name, pyrites, are excluded by definition from this process of treatment.

"Pyritic" is an adjective properly formed from pyrites. Like all adjectives, it cannot be understood in an absolute sense. It qualifies a noun and reflects either an individual opinion or a principle of classification. "Pyritic" smelting, then, means smelting, best distinguished from other smelting in some way closely related to the group of minerals called pyrites. The definition of the genus will then determine what processes are included in it. This definition will not exclude the processes described as follows: "The practice of pyrite smelting is based upon the utilization of the heat derived from the combustion of sulphide ores, in a blast furnace, in contradistinction to the heat obtained directly from carbonaceous fuel."[2] Nor with this: "We will therefore call pyritic smelting the art or practice of smelting a charge, in which all the iron present is combined with sulphur to produce a ferrous silicate slag."[3] "The allowable amount of coke in the charge is considered immaterial. A distinction based on it is only conventional."[4] On the other hand, it includes a number of closely allied processes. It will include the production of metallic copper from matte, the enrichment of mattes, as well as the production of mattes from the sulphide ores. These different processes can be distinguished from each other, but all are based on the same theory which is the standard of classification. Under this classification a furnace would not run one day on a *pure* pyritic process, and another day on a *partial* pyritic process, and we need not inquire as to the intention of the operator, or as to his knowledge of what is going on in his furnace.

### Historical Events

The Russian experiments were under the direction of M. Semmennikow, governmental head of the department. After a few preliminary tests with small quantities at the Bogolowsk copper plant (1867), they were repeated on a larger scale at the steel works near by, at Watkinsk. These tests, as to the suitability of copper mattes for the Bessemerizing process, were carried on by A. von Jossa and N. Laletin. The results, as referred to by Mr. Sticht, may be summarized as follows: The tests were made in rather small charges, but in all 18,000 lb. of matte containing 31.5 per cent Cu were treated. Fifteen tests in all were made, including the enrichment of 31.5 per cent Cu mattes to 72-80 per cent Cu, and the further refinement to 80-95 per cent Cu. The final matte was worked up on the speissofen, according to the practice of the time. The experiments were made in an oval converter, designed for Bessemerizing pig iron, which had a height of 5 ft. and a greatest diameter of 4 ft. 2 in., which treated from 1600 to 2000 lb. of matte at each "blow." The air pressure used varied from 4 to 12 pounds per square inch. High pressure involved the ejection of molten material; low pressure resulted in the closing of the tuyeres, which necessitated frequent cleaning. There were seven tuyere bricks in the bottom of the converter, each of which contained five vertical openings $^3/_8$ of an inch in diameter. In some of the experiments, all except 6 to 10 of the openings at the bottom were closed, and two supplementary horizontal tuyeres, $1^1/_2$ inches in diameter, were inserted tangentially at the bottom.

The slag formed during the operation was lifted off in chilled layers, and was not skimmed or poured.

The attempts to bring 95% Cu mattes up to metallic copper were less favorable. This was probably due to the small amount of rich matte treated, in all 720 pounds were so used, and on pouring much of it remained as a skull adhering to the walls of the converter. With a larger charge, a greater proportion could have been poured. The expedient of "double banking," i. e., blowing successive charges before pouring was not tried.

---

[2] T. A. Rickard, *Pyrite Smelting*, p. 9.

[3] Geo. A. Guess, *Eng. and Min. Jnl.*, Jan. 13, 1912

[4] Idem.

These Russian engineers clearly understood that a large part of the heat developed in the first stage of the operation (with low-grade mattes) came from the oxidation and slagging of the iron; the oxidation of $Cu_2S$ to produce metallic copper being more important in the second stage. They clearly distinguished between the two stages by the end of phenomena of color and character of flame. They were influenced, perhaps unfortunately, by the tendency of the times, to experiment extensively with the injection of steam with the blast. They were somewhat hampered by the crudity of the apparatus employed, but even in this respect they were more fortunate than other early experimenters, and were especially qualified by their experience in Bessemerizing iron and converter manipulation to conduct these experiments. The cold matte was separately melted and run into the converter.

Their conclusions, in brief, are as follows:

Bessemerizing copper matte by means of superheated steam alone, or admixed with air, is scarcely practicable. Production of black copper, 95 per cent Cu, by the application of highly compressed air, is perfectly feasible, but likely to be unprofitable, partly because of wastage of copper and partly because of accretions of copper on the converter walls. But the process of Bessemerizing low-grade copper matte is deserving of the greatest attention, and may be of the greatest utility, under the following conditions: (a) The matte should be run hot into the converter; (b) the operation should only be continued to the point where the charge consists of one equivalent of $Cu_2S$ to 0.12 of an equivalent of FeS; (c) the regulus should be brought up to black copper in the ordinary way, in a roaster furnace having a number of air tuyeres.

The advantages claimed by this new process, even thus restricted, were a notable saving of time, fuel and labor. Mr. Sticht sums up: "With these Russian experiments * * * the pneumatic process, as applied to copper mattes, was fairly launched. At all events, the availability of sulphide substances as sources of great heat under conditions which accelerate the chemical phenomena of ordinary copper smelting processes was completely established," etc.

John Hollway's experiments[5] in treating ore were made with the use of low grade Rio Tinto pyrites, at Messrs. Cammell & Co's. steel plant in 1878-9, the ordinary Bessemer paraphernalia being employed. The pyrites were melted down in a cupola furnace, and blown in regular 6 ton vessels, with 20-lb. air pressure. All phenomena were scientifically scrutinized; temperature, flame, composition of gas and molten products, etc. Among other things, he succeeded in running one converter on pyrites and quartz for fourteen consecutive hours, with repeated charging, and with the total exclusion of carbonaceous fuel, other than that used to provide the blast.

Altogether his trials demonstrated to the members of the Society of Arts, for whose benefit a special exhibition was given, "that pyrites carrying copper could be made self-smelting, and was a metallurgical fuel of the utmost efficiency; that the waste of its fuel qualities in current practice could be obviated; that a high ratio of copper concentration was achievable; that a complete utilization of atmospheric oxygen was affected," etc. Mr. Sticht regards these tests as a brilliant contribution to metallurgical art, and the report upon them as one of the classics of metallurgical literature.

The foregoing apparently successful commercial tests by Semmenikow and Hollway were not immediately followed by the building up of a new metallurgical industry, but the underlying idea inspired other investigators like Manhés and David in France, who developed the Bessemerizing of mattes. Mr. Sticht attributes the rapid expansion of pyritic smelting since 1885 to the transplanting of the process to newer fields of activity where an abundance of suitable ore, and the ingenuity of metallurgists, unhampered by conservative traditions, offered most favorable conditions. The events to be noted are:

"Six converters of the permanent plant at the Parrot Silver & Copper Co.'s works, at Butte, Montana, were completed in 1885, at the instance of Mr. Franklin Ferrell, Pres't, and under the supervision of agents of M. Manhés. Subsequently, American inventive genius, favored by economic conditions, has improved on the construction of converters and all accessories, and upon their operation. The Bessemerizing of copper mattes was thus put on a sound basis. At first, the mattes treated were kept at 35 per cent Cu, later the advantage of a 50 per cent Cu matte was seen, and this grade of matte was produced." Many workers contributed to this rapid advance. It is quite apart from my theme to award praise or to enter upon the question of priority.

To follow Mr. Sticht still further:

The urgent demands for copper mattes to keep the converters in operation directed attention anew to Hollway's experiments. "The interest in the rapid oxidation of sulphide ores, as spontaneous fuels, was revived by Mr. W. L. Austin. He with others took up the 'raw smelting' innovation, and perfected it in the new light, etc. Following in the footsteps of Mr. Hollway, and modernizing his operative scheme, the true pneumatic pyritic principle, but supported by the use of a hot blast, was at last brought to some degree of practical perfection. This was effected in Montana between 1887 and 1891, and was subsequently further pursued in Colorado."

"It was, however, reserved for Australia to demonstrate finally and conclusively that 'pyritic smelting' * * * is wholly suitable for copper ores of any grade, and is not afflicted with a greater wastefulness through scorification, or other source, than current older methods, etc. The special opportunity came at Mt. Lyell, Tasmania, in 1896, etc."

From these two nurseries, the mining regions of the Rocky Mountain states, and of Australia, the newly established industry has spread rapidly over nearly all the copper mining districts of the world. In each new field it has advanced along special lines, more or less determined by local conditions, and must be studied in each particular case in connection with these conditions.

### Progress of Pyritic Processes

The progress in pyritic smelting of copper ores, as distinguished from Bessemerizing copper mattes, may be profitably followed in the discussions of the subject carried on in the columns of the *Engineering & Mining Journal*, 1903-1905. The principal papers were published in book form under the title of "Pyrite Smelting." These carefully considered opinions of thirty or more competent metallurgists, bring out most clearly the effect of local conditions in modifying operative details. Nevertheless, there is a general concurrence of opinion upon the underlying principle.

Of the ten questions under discussion, I will only consider three: the use of a heated blast; the addition of coke to the charge, and the effect of zinc sulphide in the charge. It was generally admitted that warm or hot blast is desirable in almost every case, if it does not cost too much; that it is indispensable in some cases, and can be avoided in others. For particulars, the papers themselves should be consulted. Coke has been entirely omitted in some campaigns. In others it has been reduced to between 1 per cent and 1½ per cent of the charge, using a cold blast, when the ore ran high in pyrite. In general, smelting with 4 per cent of coke is considered good work. The practical question is this: Whether it is cheaper to furnish a hot blast, and save coke, or to use a few more per cent of coke and put up with the inconveniences which follow its use. The drawbacks to heating the blast are the cost of the hot-blast stoves and their low efficiency in raising the temperature of the blast. In pyritic smelting the gases issuing from the furnace contain too much sulphur to be used to fire the stoves, so that additional carbonaceous fuel must be burned. Some of the objections to coke in the charge, apart from its cost, and the difficulty of obtaining a suitable quality of it, in some localities, are as follows: Theoretically, and in practice, the reducing activity of carbon antagonizes the rapid oxidation of the furnace charge, which is the basis of pyritic smelting. So far, its use is irrational, but in the present state of the metallurgical art it may be admitted that in some cases it is indispensable. To burn the coke an additional amount of oxygen must be blown into the furnace, which is accompanied with nearly four times its volume of nitrogen, which makes necessary a large blast installation. As Dr. Peters expresses it,[6] "To obtain this oxidizing atmosphere we must reduce the amount of coke until, when blowing a reasonable blast into the furnace, there will be enough oxygen, not only to burn the coke, but also to produce a highly oxidizing atmosphere with which to burn the sulphide; for, when an atom of oxygen has to choose between an atom of glowing coke and an atom of glowing sulphide it prefers to combine with the coke and the sulphide simply melts as ferrous sulphide and goes into the matte as such, and it is only the excess of oxygen that acts on the sulphide." The result is an increased amount of matte and a lower ratio of concentration. The heat supplied by the coke and its reducing action is apt to be developed at a level in the furnace where they are not desired. The occurrence of iron sows and the accumulation of $Fe_3O_4$ (magnetic oxide) reported by several observers may be due to local reactions with the coke. On the other hand, Dr. Peters considers the reaction $FeS + 2FeO = 3Fe + SO_2$ as possible. This would not occur if free silica to combine with the iron oxide were present. In connection with a hot blast and the use of coke, Messrs. Lynn & Keeney, metallurgists connected with the U. S. Bureau of Mines, suggested in a paper[7] read at the September, 1913, meeting of the A. I. M. E. at Butte, the question "Whether electric heat may be used to replace the heat which is derived from the combustion of coke in pyrite and semi-pyrite processes" * * * "would it be possible and commercially feasible to carry out these processes in an electric furnace using a blast, obtaining as much heat as possible from the oxidation of the sulphur and iron and supplying by electrical energy whatever additional heat might be needed." In the discussion of this paper[8] it was suggested that this heat could be most effectively applied to the blast.

---

[5] *A New Application of Bessemer's Process of Rapid Oxidation, by Which Sulphides Are Utilized as Fuel.* Read before the Society of Arts, Feb. 12 (or 22?), 1879

The effect of zinc in the charge is generally considered negligible if it does not exceed 10 per cent to 12 per cent of the ore. It is admitted that some of it escapes at the top of the furnace, but in general an attempt is made to throw it into the slag. The fact that zinc sulphide has a considerable calorific value, as a metallurgical fuel, is however clearly brought out in the discussion.

### Further Application of Rapid Oxidation Processes

Mr. Sticht emphasises the fact that the utilization of the heat developed by the rapid oxidation of metals and metalloids in the charge by means of an injected blast of air has found application beyond the boundaries of steel and copper metallurgy. "Witness the revolution already wrought in lead smelting by the Huntington-Heberlein, Salvelsberg and Carmichael-Bradford processes and their followers," to which may be added the Dwight-Lloyd roasting furnace. "Note the renewed interest bestowed on the question of the purification of metals by means of forced oxidation. It is not too much to say that, without the precedent of the surpassing success of the pneumatic treatment applied to copper and iron sulphides, these promising departures from established tracks in other metals would have been delayed very many years."

In a second paper I shall tabulate the calorific value of the more common metals and sulphides and compare them with carbonaceous fuels, and will suggest a simple form of apparatus to experiment on the problem of burning them effectively.

Denver, Colo.

---

**Faraday Society.**—The program of the meeting of the Faraday Society, scheduled for March 27 in London, is a symposium of papers on "Optical Rotatory Power." Papers will be presented on this subject by H. Rupe, H. Grossmann, L. Tschugaeff, T. M. Lowry and T. W. Dickson, T. M. Lowry and H. H. Abram, R. H. Pickard and J. Kenyon, T. S. Patterson. Sessions are to be held in the afternoon and evening.

**The Otto Coking Company, Inc.**, a corporation, has been formed to operate in the United States, and on March 1, 1914, has taken over the organization, assets and good will of the Schniewind Coke Oven Company, the United Coke and Gas Company, the German American Coke and Gas Company and the American Coke and Gas Construction Company. The Otto Coking Company is controlled by the interests in Dr. C. Otto & Company, of Dahlhausen a. d. Ruhr, Germany, and the Otto By-Product Coke Company, of Leeds, England. The object is to introduce into the United States the Otto Regenerative By-Product Coke Oven, with direct recovery of ammonia, tar and benzol. The new company starts out with a contract for the immediate erection of a plant for the Buffalo By-Product Coke Corporation at Lackawanna, New York, near Buffalo, with several other negotiations now going on for additional plants. The permanent officers of the new corporation will be Dr. M. G. Christie, Leeds, England, President, who will spend about half his time in this country; Dr. C. Otto, Assistant to the President, who will shortly take up his permanent residence in this country, Dr. Otto being the son of the inventor of the original Otto oven. The Vice-President and General Manager will be Mr. Louis Wilputte, one of the best known coke-oven engineers in America. The Secretary and Treasurer will be George F. McKay. The temporary offices of the corporation will be at No. 6 Church Street, New York City, where they will occupy the entire seventh floor.

**Metallic zinc production** in the United States for 1913 was the greatest in the history of the country, according to the U. S. Geological Survey. Spelter from domestic ores amounted to 337,252 tons, and from foreign ores 9424 tons, making a total of 346,676 tons. This is a gain of 2.3 per cent over the output of 1912. Missouri led in production and Illinois in smelting.

# Hygiene and the Use of Ozone for Ventilation[*]

BY PROF. CZAPLEWSKI

At the congress at Frankfurt, June 10, 1909, the use of ozone for ventilation was treated by W. Cramer. Today this subject is treated in detail by myself and by Mr. Cramer, and the reason for these two reports is that after a period of praise for ozone in ventilation there has succeeded a wave of disapproval and objection. It is only just that we go over the field and see what we can say for and against ozone. The following article gives the truths about ozone and its hygienic importance in purifying and improving the air and its use in artificial ventilation.

In nature ozone is found in the air after lightning and rains during a thunderstorm. The quantities of ozone are, as Wolpert shows, so small compared to those produced artificially as to have little importance hygienically. Davy claims that this quantity is 1 mg. in 100 cbm. air; Wolpert says it is impossible to determine accurately the small quantities of ozone formed in the air, as any ozone in the atmosphere is decomposed by organic matter and gaseous impurities. The air in inhabited places is poorer in ozone than in the country, and in closed rooms the air has no ozone at all. Houzeau, Fox and Wölffhügel all attest this. The ozone percentage increases with the height above the ground. The maximum percentage of ozone is found in May, the minimum in November.

It is believed that the impurities which arise from animals and man are destroyed in the air by ozone, which is thus used up. The hygienic quality of the ozone in the air thus is of a negative character, since the air becomes purer, not because of the presence of ozone, but because the ozone is utilized to oxidize the impurities and dust particles.

Investigations on the influences of ozone on disease bacteria were taken up successfully in 1891 by Fröhlich. The work done by Ohlmüller led to this conclusion: "The ozone has a destructive action on bacteria when the water is not too much contaminated with lifeless organic substances." Sonntag was not able to prove a bactericidal effect with dry ozone, nor did Konrich get very encouraging results. Filter paper, dipped in bouillon cultures and dried, was exposed to the ozone in a glass vessel without becoming sterilized. The same was true when the bacteria were dried on glass rods, thus bacteria are not killed by dry ozone. Better results were obtained when the ozone was used on wet filter paper. There were killed in glass vessels with simultaneous moistening by steam: after 1 hour, typhoid, para-typhoid B., dysenteric, Shiga-Kruse; after 2 hours, dysentery-Flexner; after 2 to 3 hours, Coli; after 3 hours, para-typhoid B. pyocyaneous, prodigiosus, sarcina aurantiæ, sarcina flava; after 4 hours, tetragenus; after 2 to 4 hours, staphylococcus aureus (not quite certain); after 4 hours, not yet: spores of anthrax and subtilis.

Bail says there is no question that ozone dissolved in water has a bactericidal effect of the highest order, and sometimes such an effect might exist in air ozonization, as in cold storage for meats.

Kuckuck states that in the Heidelberg public bath he reduced the air bacteria 50 per cent with ozone. Labbe noticed a great decrease in the germs in the room, even with the curtains and handings drawn.

We may assume that the tests so far have not given conclusive results regarding sterilizing effect of ozone in air. More favorable results have, however, been obtained with actual ozone ventilation, especially in egg and meat cold storage plants. It is indisputable that the introduction of ozone into ventilation has resulted in better preservation of meat and prevention of moulds; the cut faces become hard and there is a saving because less of the surface cuts need be thrown away because of mould. There seems then to be an unmistakable antiseptic effect of ozone. In such operations we have, however, stronger ozone concentrations, and besides the bacteria do not grow as rapidly in the low storage temperature, are weaker, and there is the surface hardening which makes it more difficult for bacteria to procreate and thrive.

*Effect of Ozone on Dust.*—If ozonized air is passed through long glass tubes, it loses some ozone; the ozone is used for the oxidation of the organic contents in the tubes. This was found by Fox and Wolffhügel.

*Effect of Ozone on Odors.*—Erlandsen and Schwarz stated, basing their opinion on the fact that the odors reappeared, that it is a matter of covering odor, not removing odor, and that we deal with a similar case when decaying material or fecal matter is covered with carbolic acid, and the latter odor overcomes the former without destroying it.

The two opinions, destruction of odor and covering of odor, stand diametrically opposite to each other. Konrich goes, perhaps, farthest when he ascribes to ozone merely a perfuming effect.

*Disposal of Odor.*—Most chemical substances have some odor, and many are scents, often very powerful; some are simple, others complex. Among the simple scents are chlorine, bromine, hydrogen sulphide, iodoform, and among the more complex, merkaptane, indole, skatole, trimethylamine, etc. There are substances which do not themselves smell but which become odorous under the influence of heat or moisture, e.g.: trioxymetheline in itself is odorless, but when decomposed gives a strong, penetrating formaldehyde odor; hydrogen sulphide is produced by the decay and decomposition of sulphurous metals and alkalies.

In the disposal of odors we differentiate between odor distributed in the room, that can be removed by ventilation, and fixed odor, or odorous substances that cause odors and are, therefore, permanent sources, as, e.g., odor *fixed* on the surfaces of objects in the room. This depends on the *quality* of the surfaces, whether of porous or impervious materials. With smooth and impervious surfaces, as metal, glass, porcelain, stone, oil coatings, furniture polish, varnishes and lacquers, we must consider also their heat conductivity. When they cool there may be a deposit of moisture through condensation of water vapor, which occurs the more rapidly the greater their specific heat and conductivity coefficient.

With pervious materials we must differentiate between porous and hygroscopic properties. The former absorb air and water vapor only into their pores, the the latter absorb water vapor and with it, probably also, dissolved gaseous substances. When the temperature is lowered the air or water vapor enclosed in the pores contracts; when the temperature rises the volume increases and liberates the water vapor and the absorbed gases. This is important in connection with the appearance of obstinate after-odors. Of the hygroscopic substances, animal textures like wool, silk, hair, fur and less so the vegetable textures like cotton, linen, pure cellulose, absorb odors readily. The persistent odors which cling to clothing and hair after exposure to tobacco smoke often prove as disagreeable as does cold smoke itself.

We must deal, therefore, with simple absorption, in porous surfaces and also possibly with a chemical action as through hygroscopic surfaces. We must also consider the character and area of the surface, which depend a good deal on the surface development in the room. Odors will stick much longer to rough, porous walls whitewashed and coated with linseed paint, hangings, tapestries, upholstered furniture, because these absorb them, while smooth and impervious walls, smooth furniture, lack of hangings, etc., facilitate the removal of odors. We first dispose of the source of the odor, but this is difficult if we have walls saturated with odors as sources. Results might be obtained in this case by driving the odors out of the walls, by increasing the temperature and distilling them out and then treating the free odors with ozone.

---

[*] A lecture held at the Ninth Congress for Heating and Ventilating at Cologne, 1913 Translated in abstract by Dr. M W. Franklin.

*Hiding or Covering of Odors.*—In effective concentrations ozone can destroy certain odors through oxidation, as we can prove beyond a doubt for hydrogen sulphide, indole, skatole and decayed matter. If the odor appears after the ozone is removed the after-odor is due to the residues of the odors absorbed by the walls, carpets, furniture, upholstery, etc., and which were protected from the ozone by their depth. Of great importance for the explanation of after-odors are the experiments of Lehman and Kisskalt as to the absorption of scents. When Kisskalt brought dry ammonia vapor into a room so much was absorbed that even after two to three weeks several grams per day passed back into the air.

*Tests to Remove Odors with Ozone.*—Hill and Flack found ozone to be powerful in removing odors. They filled their test room with tobacco, ammonia sulphate, carbon disulphide vapors, human excrements or putrefied meat, and they were not able to discover the odor after two minutes of ozonation.

Erlandsen & Schwarz and L. Schwarz had no great success in their tests in large rooms, although the latter states that large quantities of ozone in truth deodorize the room. In general, scents and odorous substances, which are clearly defined chemically and simply constituted, as hydrogen sulphide, sulphur dioxide, ammonia, indole, skatole, iodoform, etc., are destroyed by ozone.

*Ozone and Hydrogen Sulphide.*—Kisskalt found hydrogen sulphide to be decomposed in the air, with ozone in excess. Erlandsen and Schwarz proved that ozone destroys the hydrogen sulphide odor.

*Ozone and Sulphur Dioxide.*—Schwarz and Münchmeyer showed that an excess of ozone would react with at least part of the $SO_2$ and form sulphuric acid.

*Ozone and Indole, Skatole.*—Erlandsen and Schwarz found indole and skatole odors greatly reduced and even absent. Kisskalt treated a room smelling stuffy and damp, and with whitewashed walls, with ozone, 0.37664 mg. per cbm. (= 0.1883 per million), and skatole was evaporated over a gas lamp. He concluded that the skatole odor had been destroyed by the ozone. Schwarz and Münchmeyer in quantitative tests found indole and skatole destroyed in a short time with an excess of ozone. In the control tests there was a strong skatole and indole odor, while with ozone there was an agreeable, etherlike odor.

*Ozone and Merkaptane.*—Schwarz and Münchmeyer found that merkaptane is easily oxidized by ozone.

*Ozone and Trimethylamine.*—Erlandsen and Schwarz could not destroy the trimethylamine odor with ozone, but they evaporated 5 cc. of a 33 per cent aqueous solution in a room with less than 15 cbm. contents.

*Ozone and Butyric Acid.*—The smell of butyric acid was removed after 70 minutes' action of ozone. After an hour the smell returned, however, and was present even on the next day. Kisskalt found that butyric acid vapors in the air had not combined chemically with the ozone after 50 minutes.

*Ozone and Iodoform.*—Tests of Dr. J. Muller in the Nüremberg City Hospital demonstrated that the smell of iodoform is removed by ozone.

*Experiments of Bail.*—Bail found that with ozone in the small quantities possible in ventilation the odor of evaporated decayed matter was strongly affected after removing the source of the smell. The nauseating character of the odor disappeared, leaving behind only a persistent glue odor. He noticed that the ozone smell always appeared later, while the air took on a peculiar "fresh" characteristic. (This coincides with the views of Cramer, Hill and Flack.) The later appearance of the ozone odor indicates that ozone is used for the oxidation of the odorous matter and can appear only after having removed this. The original smell is made of a number of individual odors, some of which oxidize and leave the glue odor behind. They did not reappear after stopping the ozone supply so that they must have been destroyed.

"We may conclude, therefore, that small quantities of ozone, practically used, can destroy certain disagreeable odors in the air, and there is no reason to doubt that the excrements and their odors can be influenced by ozone. Through this fact we could explain the excellent results obtained by Lübert and others with ozone in theatres, halls, etc."

*Ozone and Tobacco Smoke.*—Of greatest interest, on account of its application to restaurants, is the influence of ozone on tobacco. Cramer says: "If we blow ozone into a glass tube filled with tobacco smoke the smoke conglomerates and soon disappears."

Hill and Flack were able to dispose of tobacco smoke through ozone. Erlandsen and Schwarz saw no influence of ozone on very heavy tobacco smoke, though in weaker concentrations the smoke was "covered over" by the ozone. In our own tests with strong ozone concentrations, cigarette smoke was entirely destroyed in a room and could not be perceived after re-entering the room, as there was no after-smell. Tobacco smoke on clothing is disposed of by the ozone. Konrich says that ozone has only a perfuming action, without destroying the smelling substances, but it is impossible to substantiate his opinion in view of the exact tests of Kisskalt and of Schwarz and Münchmeyer.

*Is Ozone Poisonous?*—Much excitement has resulted from the cry that ozone is a poisonous gas. Hill and Flack, as also Konrich, have made a considerable stir in this direction and it is therefore necessary to go more fully into their work. All agree that weaker ozone concentrations have no harmful effect at all, while stronger concentrations produce more or less local irritation of the mucous membranes. Schultz believed that the ozone went directly into the blood and worked secondarily on the lungs. This opinion was disposed of by Bohr and Maar, who showed that the lobe of the lungs influenced by strong ozone became irritated, while the other half, treated with ordinary air, remained normal. Pflüger states that ozone in contact with blood is immediately destroyed. Cramer said at the Frankfurt Congress for Heating and Ventilating: "In earlier times we assigned to ozone a poisonous influence on animal organisms, while recent investigations have shown that the ozone is poisonous only when made chemically and not pure. A mixture of chemically pure ozone with atmospheric air can, if the percentage of ozone is not too concentrated, never hurt an organism, as statements from doctors and scientists show. Only in very concentrated form does it attack the lining of the mucous membrane."

Hill and Flack state that the only action of ozone is that it causes irritation of the lungs if inhaled in strong concentrations for a considerable time, and that the danger signals are well set. These authors report tests with rats, cats, dogs, goats and mice. The animals were placed in airtight glass chambers and the ozone varied between 2 to 40 parts per million. They conclude that animals die when exposed to 15-20 millionths parts for two hours, but this does not coincide with their table wherein a dog and three rats recovered after exposure to this quantity. The causes of death were inflammation of the respiratory tracts, blood congestion in the lungs and edema of the lungs. Microscopically the alveolæ showed inflammatory exudations and hemorrhages. There were no other changes in the body.

There are several objections to these tests. First, it is not certain that their accounts of the ozone concentrations were correct; they determined the ozone in acidic potassium iodide solution (1 per cent), and this gives too high ozone value; also their method of using only 10 liters of air in the determinations is questionable. The judgment of such animal tests as regards the poisonous quality of the ozone is moreover very difficult. There are no figures to show the size of the experimental chamber, the quantities of air passed, nor the circulation. With their tests on odor disposal they placed two ozonators at the ceiling of the experimental chamber, but in the animal tests these points are not mentioned. There are no indications of the capacity of the ozonators. Through all these omissions it is difficult to see whether the disturbances in the animals are due to the ozone alone, or whether other causes like insufficient ventilation, excess of heat and carbon dioxide poisoning are to be added, nor do we know that the authors did not use ozone free from nitric oxides, therefore we cannot regard these proofs very highly. Hill and Flack used enormous concentrations in their animal tests, which by far transcend the quantities ever used in practice, and yet they have not always led to death.

*Animal Tests of Konrich.*—Konrich used a glass chamber 44 cm. long and 20 cm. wide and 18 cm. high, equal to 15,140 ccm., and gives accurate results of his seven tests. The ozone was produced in a grate ozonator and passed into the chambers under special precautions. He used rabbits, guinea pigs, white rats and mice.

There are many objections that can be brought against these experiments. The animals were in a comparatively small space, in some tests too many animals were in the chamber (1 rabbit, 2 guinea pigs and 4 rats); the quantity of air was 13.5 to 73.62 liters per hour, which is very little. The change of air was therefore in one case less than one time per hour; three times, more than twice per hour, and twice, more than two times per hour. Only in the last tests were the changes more than 4.6 times per hour, but in this test the ozone concentration was very high (0.23 gms. per cbm.). These facts give rise to the opinion that they died through other influences than ozone, as $CO_2$ poisoning, excess of heat, etc., a good quantity of the 16 liters of air being used by the animals. It may be that there are other causes, as for example, nitric oxides or nitrous vapors, as seems possible from the appearance of the lungs. My conclusions on this last fact are based on experience I obtained in the poison cases, through nitrous vapors, in Cologne. My suspicions were further confirmed by Von Kupffer, who stated that it is possible for nitrous vapors to have been formed as Konrich did not cool his ozonator grate frequently.

That pure ozone is not dangerous to small animals was proved by Sigmund. Labbé and Oudin call attention to the fact that chemically prepared ozone is always impure and often has constituents like phosphorous acid. When we approach natural conditions in treating animals with a mixture of atmospheric air and ozone we find no harmful effect. Labbé says: "Among the numerous ozonators there are very few that can produce a pure ozone in quantities that have been determined to be correct by tests. Moreover, it is very important to avoid the production of nitrous products as otherwise there will be caused irritations."

*Konrich's Tests with Human Subjects.*—The experimental chamber of glass and wood with air-tight doors has 3.8 sbm. capacity. A grate ozonator and electric ventilator were used. Through special valves the changes could be made so as to stagnate the air, circulate it, ozonize, remove this air and change by fresh air, bring in partly used, partly fresh air; ozonized and circulated air; air removed and then filling the chamber with fresh air. In the chamber there were one or two persons who remained from 40 minutes to 4 hours 35 minutes. In the tests with stronger concentrations the ozone varied between 0.431 and 6.72 mg. per cbm. Through adding steam the air in the chamber could be saturated with moisture. In other tests the air was dried and in some cases heated.

Konrich calls attention to the fact that the tests with people give the same results as those with animals, only that the irritations of the respiratory organs are more in evidence, and he adds that the sensitiveness towards the ozone is very different individually. The mucous membrane seems to be more irritated when the air is dry; when the air is very moist the presence of ozone is less irritating, and it is not as perceptible as an odor. The subjects suffered considerable inconveniences and trouble physically, but it is questionable whether these were due to ozone or to the other causes.

This question, according to my opinion, must be answered negatively. The tests were made in an abnormally small space, usually without air renewal, only the room air being ozonized. That the air in the chamber was vitiated to the highest degree is not surprising, and this is shown by the high increase of carbon dioxide content. We may assume, moreover, that the $CO_2$ at the floor level was even worse; the temperature also was very high (21 to 25 deg. C.); the humidity varied between 60 per cent and 90 per cent. Konrich thought the dry air increased the irritability of the membranes to the ozone, so he humidified the air with steam.

We cannot very well call air of 66 per cent to 68 per cent, or even 60 per cent, relatively dry. Esmarch says that a room with 30 per cent to 60 per cent relative moisture is hygienically proper. The percentages above 60 are therefore high. In test (7) the humidity rises to 80 per cent and then to 100 per cent, then after 12 o'clock 13 per cent to 25 per cent steam is admitted, whereupon the ozone odor is reduced and the burning of the eyes, also the coughing, are decreased.

Why more steam was admitted is not clear, since there was enough moisture without this addition; at this time the temperature was 30 deg. C. at 80 per cent humidity. This is a tropical climate artificially produced, and it caused trouble through excess of heat and the high humidity factor and its influence on respiration and on evaporation from the skin. To this must be added the poisonous effect of the $CO_2$. The calcium chloride drying apparatus was able to reduce the moisture only to 55-66 per cent, which is still too moist; however, the temperature was relatively low (18 to 20.5), while in the other cases it was 25.5 deg. to 29 deg. C.

I am nowise inclined to state that ozone is not harmful when used in very strong concentrations, and that it then could not irritate. We know the intensive action of ozone from water sterilization and we can easily demonstrate its chemical action, but I do not think the phenomena in these tests are pure ozone effects, as there are many other factors that enter. Labbé and Oudin, moreover, noticed in the production of ozone the phenomena of metal vaporizations, and it is well known that metallic vapors have a strongly irritating action and are very poisonous.

*Author's Tests.*—I, personally, made some tests with ozone. Two systems were used, the one in the abbatoir of Mühlhausen, using a large central ozone ventilating plant with water cooling device, the other with two local ozone generators without cooling. Low concentrations were found pleasant whilst stronger concentrations of ozone caused more or less irritations. Several persons claimed that with stronger concentrations they felt tired, faint and had headaches. After longer exposure in the rooms with stronger ozone concentrations they felt, on the next day, physically tired, but in these cases there were used concentrations which could not be used practically even in the worst cases, one test showing 2.7 *grams* ozone and 1 cbm. air. No really serious disturbances were noticed, though several times it was possible to smell an after-odor of ozone absorbed by clothing.

*Results from Practice.*—The preceding results show that there are no valid grounds for considering ozone a poisonous gas and this opinion is strengthened by the results of wide experience and practice. These particular results are all the more important since in them the ozone is not dealt with *milligrams* but in *grams.* It cannot be denied, moreover, that many times workers are exposed to high doses of ozone without being hurt.

Erlwein says: "It is a fact at any rate that there have never been proven cases of sickness of a serious character due to breathing ozone air. Special attention is called to a large water sterilization plant operating for more than ten years, where the working force is constantly moving in an atmosphere which is many times more strongly mixed with ozone than is ever found in actual ozone ventilation installations. There has never been a case where these persons have been on sick leave due to the high ozone concentrations."

*Use of Ozone for Ventilation.*—We come now to the use of ozone in ventilation. The air in closed rooms vitiates:

(1) Through respiration of the lungs, the liberation of carbon dioxide, liberation of water vapor, increase of temperature, perspiration from the skin, liberation of various exhalations, scents, among them probably the fatty acids.

(2) Illumination vitiates the air through increase of temperature, liberation of $CO_2$ and of odors, as petroleum.

(3) The admixture of other odors, as odors of food, tobacco, etc.

In the main we deal with an increase of the humidity, the carbon dioxide percentage, a decrease of oxygen and the vitiation of the air with disagreeable, offensive odors. Especially bad is this in assembly halls, restaurants and steerage decks. This vitiation of air is not only unpleasant but dangerous, and leads to poor breathing and faulty nutrition and digestion. Sensitiveness to odors varies and cannot be taken as a good indicator of bad air, as we get used to the bad air and it is only when we step out into the fresh air and then return that we notice it in the room. The air of uninhabited rooms becomes stuffy and close, due to the exudations of the walls and objects in the room, owing to lack of ventilation.

*Ozone for Ventilation of Human Habitations.*—As we need the oxygen in the air for our life processes, and as we can use the same only in the pure, uncontaminated state from the outside, we must resort to the latter to supply our rooms with fresh air. The only safe method of obtaining this is an efficient ventilation installation, but since it is not always easy to obtain perfect ventilation, ozone has been used in many cases as a very helpful ally, and within a comparatively short time there have been installed a large number of ozone ventilation plants.

We differentiate between: (1) ventilation with ozonized fresh air, and (2) ozonization of the room air. The former is preferable from the hygienic standpoint.

The favorable effect of ozone in cafés, restaurants, theatres and halls has been highly lauded. The ventilation of the subways is also a success. Lübbert has had splendid results with one of the most difficult subjects, the ventilation of emigrant ships. With closed windows the ozonator was able to maintain a tolerable air condition, which, without the apparatus, yas unbearable. Regarding these tests of Lübbert, Konrich states that there were no complaints as to irritations from ozone.

Ozone is also recommended for public baths, which have, in spite of ventilation, a peculiar odor, made up of a number of simpler odors. The exudations of the skin with their fatty acids, the smell of the soap, of the water, of the wet mats, the wet woodwork, the wet walls and objects, all add in bringing about this odor. Kuckuck, in Heidelberg, has succeeded in disposing of this smell with ozone, and the same has been done in Breslau. The bath smell is superseded by that of fresh bleached wash.

Erlwein states that in dissecting rooms it has been possible to decrease the odor of dead bodies considerably.

It is necessary in weaving and textile mills to have a high degree of humidity, which has a very injurious effect on the workers, for with high humidity and temperature, evaporation and radiation from the skin are lessened and the body is unable to cool properly, and there results fatigue and reduced efficiency. Considerations of cost forced certain plants to work in the winter with recirculated air, which of course was partly vitiated, and, although again purified, it was unable to substitute for all the good characteristics of fresh air. Great success was attained when ozone was added to the fresh air.

*Ozone in Industrial Plants.*—A great field for ozone ventilation is open in the food industry, especially in the cold storage chambers of abattoirs. Ozone has caused direct saving in such plants, since the meat remains fresh and good for a longer time. In egg cold storage the ozone has given excellent results in that the disagreeable straw and box odor disappears, fewer eggs decay and the eggs last longer. The manager of the Cologne abattoir says: "Meat that had gone over into partial decay was to a certain degree recovered when the ozonator worked, and the mould coating disappeared."

Konrich reports on an ozonator plant in the Berlin abattoir, in the entrail cleaning room: "In this plant they were proud to state that the complaints of the neighborhood as to the stench from this part of the plant had disappeared. The same plant is also meant by Erlwein in his favorable report on an abattoir. Ventilation, as also an attempt to remove the odor by means of coke filter beds, were failures. The remedy was found when the gases rising through the chimneys were first passed through a duct with concentrated ozone. There is no trace of the former intensive odors. The expensive ventilation was removed and the plant was reported to be in perfect shape by the inspection department."

I might add to this that in the local city there is an abattoir with such a department and that one-half of the same works with ozonator, the other half without. A visit to both sides will easily permit the proper conclusions to be drawn. Konrich reports an ozonator plant in a herring packing establishment, where the success lay in the prevention of mould formation in the store room.

Vetter found that in breweries ozone could be used to purify bottles, barrels, to clean pipe lines and apparatus, after preceding mechanical cleaning. Filter cloths and yeast bags that could not be sterilized by means of steaming and boiling, were sterilized by exposing them for one hour to the ozone.

*Quantity of Ozone.*—The question of ozone concentration is a very important one.

*Lack of Standard Method of Ozone Determination.*—In looking through the literature the author was surprised to see the lack of uniformity in determining ozone quantitatively and found himself unable to draw valid conclusions from different tests or to compare them properly because of the variety of procedures employed.

For quantitative determination the KI method is usually used. A review of the different methods shows that there is no uniform determination. A uniform method is absolutely necessary, for the practical results of an ozone plant depend on proper concentration. A standard method should give detailed directions as to absorption liquid, concentration, reaction, quantity relations, form and size of measuring instruments, manner and length of passage of air, titration, etc. As the creation of such a *standard* method seems to me to be the *first fundamental requirement for scientific and proper advancement in ozone problems,* I would advocate starting a prize contest for the best and most accurate method of ozone determination which can be adopted as standard. A standard method of determination should be so delicate as to detect even the minutest quantity of ozone for whose determination we are at present restricted to the senses which are at best inaccurate. The ideal would be a method which would accomplish this with even a small quantity of air as 10 to 50 liters and give the results in a few minutes.

*When Are We to Ozonize?*—Konrich says: "We cannot answer this question in a general way. If the ozone is sent to the rooms through a central ventilating plant, weak concentrations can be used during the performance in the case of a theatre."

Personally I would like to add to this that we can expect successful results only if we use the ozone ventilation plant frequently, until the walls of the room are saturated with this fresh ozonized air. In inhabitated rooms we can ozonize only in weak concentrations, but with uninhabitated rooms there is no reason why we cannot use stronger concentrations, using them either before or after occupation, or both.

*Value of Ozonization of Air.*—Director Gutman, Stuttgart says: "It is not sufficient by any means, as has often been tried, to send ozone to a room regardless of its distribution, for then we usually have an over-ozonization of some rooms and an under-ozonization of others. This is clear when we recollect that we merely want to purify the air and require, therefore, only a certain quantity of ozone at any one point in the room. To bring in more ozone is useless and in excess cases even disagreeable."

*Conclusion.*—We may sum up all the points considered in the following way:

(1) Ozone is an intensely active gas. Its effect depends on its high power of oxidation. It acts more powerfully wet than dry. Energetic effects are obtained in high concentrations only.

(2) As regards the air purifying properties claimed for the gas we have: (a) We need not count on a destruction of bacteria in the air by ozone, nor their destruction on the walls of rooms, nor on objects in the room. (b) There is no oxidation of the organic dust particles. (c) There is, however, a positive effect on certain scents and the odors given off by the same. Some odors are destroyed, others are weakened. At times we obtain disagreeable mixed odors. After-odors are to be referred back in part at least to the odors absorbed by walls and objects in the room and later diffused outward.

(3) The effects of ozone on man depend on the concentration. In small and weak concentrations the effects are agreeable and are found to be refreshing and entirely without danger. In stronger concentrations the ozone irritates the mucous membranes and especially the respiratory tracts. The sensitiveness differs and is often increased through inflammation of the mucous membrane.

(4) Whether the cases of death in animals and sickening effects in man are due to the ozone alone is a matter of doubt. Care should be taken at least to see that the ozone is pure and has no nitric oxides and nitrous acid.

(5) In ozonization of air we must differentiate between (a) ventilation with ozonized fresh air (best central ventilation); (b) ozonization of enclosed room air. The former is preferable without question, and is the only one that need be considered in the development of the ozone ventilator problem. Ozonization of room air is often only a makeshift of dubious value. Tests with ozonization of room air allow no very valid conclusions which might be applied to the ventilation of rooms using ozonized fresh air.

(6) For ventilation with people in the rooms only the weakest concentrations are to be used, such as lead to no complaints by the people.

(7) Strong concentrations are to be used only when no persons are in the rooms, or in rooms used only for a short time. They are possible for industrial plants (although here temporary high concentrations may be used without danger or permanent injury).

(8) On no account does ozonization permit the curtailing of ventilation. Good ventilation is the first prerequisite. Ventilation can be improved by combining it with ozonization.

(9) With these suppositions and under these conditions, the use of ozone in the air seems not only permissible but even advantageous, especially in industrial operations and plants.

(10) The peculiar contradictions between the favorable practical results and the results of many laboratory experiments should be cleared up by further research.

(11) For this we need in the first place a standard method of ozone determination.

(12) A standard nomenclature for the ozone concentration is also desirable.

---

**Prizes for Highway Study.**—To encourage investigation of methods and materials for road and street construction, and to interest engineering students in highway problems, The Barber Asphalt Paving Company of Philadelphia, Pa., has offered prizes of $100 for the best paper written by a member of the graduating classes of the leading engineering schools. The title suggested is "Asphaltic Materials for Highway Construction." The paper and its conclusions may be based upon service tests and the lessons of experience; the physical qualities or chemistry of asphalt; or it may combine any two of these lines of investigation. The length of the paper is limited to 3,000 words and all manuscripts must be received not later than June 1, 1914. The purpose of this prize offer is to turn the attention of engineering students to street and road construction as a field of work in which there is great need and great opportunity for trained men.

The Bunker Hill & Sullivan Mining Co. is having "moving pictures" made of all its operations in mining and milling. Underground operations will be photographed by the aid of a powerful electric light. The completed pictures will show the treatment of the ore by concentration from crushing to shipment of concentrates. It is reported that the films will be placed at the disposal of mining schools.

## The Iron and Steel Market

The iron and steel markets became more and more quiet during March, until at the close of the month a state bordering on stagnation was reached. Strictly new buying became almost nil, and by the middle of the month specifications on contracts had dropped to 50 or 60 per cent of the rate obtaining in February.

The rate of steel production has not been decreased as a result of the smaller flow of shipping orders, and remains, as an average of the whole industry, at between 70 and 75 per cent of capacity, but there is no question that production will very soon have to be curtailed if demand does not improve. In some lines the mills have orders on books sufficient to enable them to maintain the pace of production for a month or longer, and the tin plate mills are still more strongly fortified, but in some lines a curtailment in output early in April is rather probable.

The steel trade has been at a loss to account for the loss in market activity in March. The lull in new buying which developed in February was expected, after the fairly heavy January buying, but a decisive improvement was fully expected before the close of March in anticipation of spring and the resumption of outdoor work on a large scale. A part of the quietness has been attributed to general timidity in business circles on account of legislative uncertainties at Washington in connection with the anti-trust bills, while a part is ascribed to a waiting attitude on the part of the railroads, due to the pendency of their demand before the Interstate Commerce Commission for an advance in freight rates. While these theories early found general acceptance, it has since become evident that some other influence must also be at work, for even in the midst of these conditions there should be more buying than has occurred during the second half of March, and there is reason to suspect that this other influence is that many buyers have adopted a theory that steel prices are going to be lower before they are higher. There are some good grounds for such a theory. Prices were advanced rather generally at the beginning of February, on the basis of the buying which had occurred in January, and to support such advances further good buying would naturally be required, and such buying has not occurred. In addition there is the condition that many contracts were written for the second quarter at $1 a ton advance over first quarter prices. To make such contracts enforcible the general market would have to advance, and when it does not the result is that the business will have to be written over again. With a fresh period of competition for this business the whole price question would be reopened.

While steel prices did not definitely decline in March to any extent, there was softening in the case of several products, and plates and shapes became quotable at $1 a ton lower than at the close of February.

### Pig Iron

The market has become extremely quiet in all districts. In some cases furnaces have attempted to advance prices, but the advanced quotations must be recognized as purely nominal, since buyers evince no tendency to take hold. Indeed, there is the development that shipments against contracts are in some cases not being taken at the full rate. A few merchant furnaces are understood to be considering the question of blowing out in the near future, as soon as enough iron has been accumulated to take care of contracts now on books. Inasmuch as the merchant furnaces as a whole have not increased their production since the first of the year, while the steel interests have largely increased their pig-iron output, the country's requirements in merchant pig iron must be quite limited. The market stands quotable as follows: No. 2 foundry, f.o.b. Birmingham, $10.75; No. 2 foundry, delivered Philadelphia, $15 to $15.25; No. 2 foundry, f.o.b. furnace, Buffalo, $13.25 to $13.75; No. 2 foundry, delivered Cleveland, $13.75; No. 2 foundry, f.o.b. Chicago furnaces, $14.25; at Valley furnaces (90 cents higher delivered Pittsburgh), Bessemer, $14.25; basic, $13; No. 2 foundry and malleable, $13.25; gray forge, $12.75. Ferromanganese is nominally quoted at $39, Baltimore, but the price on both prompt and contract can usually be cut to $38.

### Steel

The market in billets and sheet bars has been practically stagnant. When the mills advanced prices about the beginning of February their new quoting level was $21 for first quarter delivery and $22 for second quarter delivery on billets, with $1 extra for sheet bars. Thus the market should really advance $1 a ton on April 1, but conditions in the general trade hardly support an advance at this time. The sheet mills are indisposed to pay an advance as their market has tended to weakness rather than to strength during March. There has been no important inquiry to test the quotation for second quarter. Rods are $26 to $27, Pittsburgh.

### Finished Steel

Prices named below are f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.15c. to 1.20c.

Shapes, 1.20c. to 1.25c.

Steel bars, 1.20c., base.

Iron bars, 1.35c., Pittsburgh; 1.27½c. to 1.32½c., Philadelphia; 1.15c. to 1.17½c., Chicago.

Wire nails, $1.60 per keg, base; plain wire, 1.40c., base.

Sheets, blue annealed, 10 gage, 1.40c.; black, 28 gage, 1.95c.; galvanized, 28 gage, 2.95c.; painted corrugated, 28 gage, 2.15c.; galvanized corrugated, 28 gage, 3.00c.

Merchant steel pipe, ¾ to 3 in., 79½ per cent off list.

Steel boiler tubes, 3½ to 4½ in., 71 per cent off list.

Standard railroad spikes, 1.45c., Pittsburgh; 1.50c., Chicago.

Structural rivets, 1.70c.; boiler rivets, 1.80c.

Cold rolled shafting, 64 per cent off list.

---

## The Non-Ferrous Metal Market

Dullness characterized the non-ferrous metal markets during March. Buyers held aloof generally, seeming to be well covered for immediate needs. Prices quoted were not adhered to strictly, and producers were willing to make concessions to get business. On account of the accumulation of stocks, producers have exerted some pressure to sell.

Copper.—Business in Lake copper is in the hands of but one or two producers, and they continue to get their asking price. Quotations are nominal, however, as the same conditions prevail that have obtained for some months past. Considerable business has been done in electrolytic, but at reduced prices. Domestic consumption has exceeded foreign. Electrolytic now stands at about 14.07.

Tin.—An almost entire absence of demand characterizes this market, and consumers are apparently well supplied. The prices are low and conditions are favorable for a buying movement. March tin is quoted at 37½ cents.

Lead.—The American Smelting & Refining Co. continues to ask 4 cents for lead, which is the New York quotation. Business at St. Louis has been done at 3.90 cents, and quotations are given as 3.87½ to 3.92½ cents.

**Spelter.**—Prices are lower and a larger tonnage is reported sold. It has been supposed that accumulation of stocks in smelters' hands has caused them to reduce the price to a point that would attract business. St. Louis quotations are 5.10 to 5.12½ cents, and New York 5.25 to 5.27½ cents.

**Other Metals.**—The market for aluminium continues dull, with only moderate sales. No. 1 ingots are quoted at 18½ to 19 cents per pound, New York. Only a fair demand exists for antimony, and quotations vary from 6 to 7.35 cents for various brands. Business is good in quicksilver. The New York quotation is $39 per flask of 75 lb. San Francisco price is $38.50 per flask for domestic orders.

## Recent Chemical and Metallurgical Patents

### Gold and Silver

**Slime Filter.**—That all the possible modifications of continuous vacuum filters have not yet been considered is shown by the patent granted to Mr. James Drage, of Boulder, Western Australia. A four-stage machine is shown in longitudinal section in Fig. 1, and in transverse section in Fig. 2, the latter being on the line *ab* of Fig. 1. The object of the machine is to provide a series of filters, each with its agitating and filtering tank, for the successive washing of an ore pulp with several solutions or water washes. The filtering units proper are arranged in an annular ring around the periphery of a wheel. Each of the units is connected with sources of vacuum and pressure, so that as the wheel revolves the filter units that are submerged in slime pulp will be under pressure, thereby removing the liquid and forming a cake of solid on the filter fabric; on emerging from the pulp the units come under pressure so that the cake is discharged. Suitable means are provided to direct the discharged cake into the mixing and agitating tank of the next filter, where the same operation takes place, and so on through the four stages.

Referring to the cuts, the filter wheel is represented by 3, and the filtering units by 17. Pipes from each unit to the central valve connecting with vacuum and pressure are shown at 14. From left to right, each filter has an agitating tank with agitator 25, wherein the pulp is kept at a uniform consistency. Perforated partitions 23 are placed between the agitating tanks and the filtering-tanks, as shown in Fig. 2. The pulp flows freely from the agitating to the filtering tank through perforations as shown. The filtered and washed pulp is discharged from the machine at 36, after having received several treatments. (1,087,647, Feb. 17, 1914.)

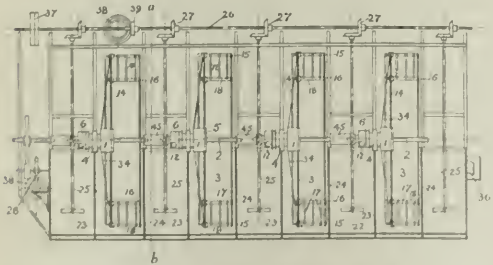

FIG. 1—FOUR-STAGE VACUUM FILTER

### Copper

**Hydrometallurgical Process.**—Mr. Edward R. Weidlein, of Pittsburgh, Pa., has invented a process for the recovery of copper in the wet way, based generally on the reversible reaction

$$CuSO_4 + SO_2 + 2H_2O = Cu + 2H_2SO_4.$$

The mode of operation is said to make this reaction of great commercial importance, because copper can be precipitated from its solution substantially quantitatively in metallic form. Ore is leached with a solution containing 3.6 per cent sulphuric acid, whereby copper is taken into solution and the free acid content is reduced to less than 1 per cent. The free acid is neutralized by lime or other base, and the precipitate of calcium sulphate removed by filtration or otherwise. The copper sulphate solution, containing say 1.5 per cent copper, is then treated in a tower, for example, with sulphur dioxide gas, until the concentration of the latter in the solution is the same as that of copper, viz., 1.5 per cent. The solution is then led to preciptating tanks where it is heated to a temperature of 150 deg. C., giving a pressure of 100 lb. per square inch. Under these conditions of temperature and pressure, copper is precipitated in finely divided form, and can be removed by filtration. It will be noted that sulphuric acid is regenerated in the reaction, and the solution can be used for further leaching. Iron will not be precipitated under the conditions given. Ferric salts in solution will be reduced to the ferrous state, becoming solvents for copper. (1,089,096, Mar. 3, 1914.)

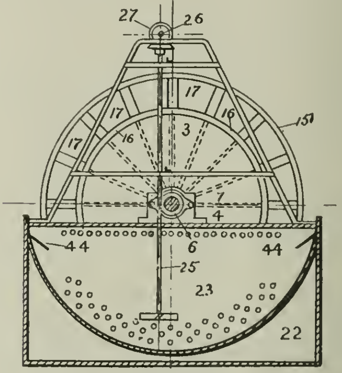

FIG. 2—SECTION OF FOUR-STAGE VACUUM FILTER

### Rare Elements

**Reduction of Rare Elements from their Oxides.**—Processes usually used for the reduction of zirconium, thorium, titanium, cerium, vanadium, uranium, tungsten and molybdenum, have been based on a reaction between sodium and chlorides of the metals mentioned. Direct reduction from their oxides was disadvantageous because the alkaline metals distilled at the high temperatures employed. According to a patented invention of Mr. Hans Kuzel, of Baden, near Vienna, Austria-Hungary, and Edgar Wedekind, of Strassburg, Germany, the direct reduction of these metals from their oxides can be accomplished by treatment with metallic calcium at high temperatures, say 800 deg. C., or more.

Thus, in the production of pure zirconium, 50 grams of its oxide is intimately mixed with 72 grams of metallic calcium, and the mixture is heated in a metallic bomb under vacuum. The reaction proceeds rapidly. On completion, the bomb is cooled and then opened in an atmosphere preferably free from oxygen and nitrogen. The mass is treated with water and then dilute acid to bring all calcium into solution. The insoluble residue is filtered and dried, preferably in a vacuum, at a temperature of 300 deg. or 400 deg. C. The product will be 96 per cent zirconium, about 3 per cent zirconium oxide and other impurities. The properties of the element thus prepared differ from those announced heretofore, and the inventors ascribe the difference to the fact that former investigators have not produced pure zirconium. (1,088,909, Mar. 3, 1914.)

**Extracting Thoria from Monazite Sand.**—The production of thoria in such condition as to be available for use in the preparation of the Welsbach mantle, is the object of a process patented by **Mr. Charles Baskerville**, of New York City. The general composition of monazite is given in round numbers as follows:

| | |
|---|---|
| $P_2O$ | 29.0 per cent. |
| $Ce_2O_3$(earths) | 31.0 " " |
| $Di_2O_3$(earths) | 31.0 " " |
| $SiO_2$ | 1.5 " " |
| $ThO_2$ | 6.5 " " |

The invention contemplates the reduction and volatilization of the phosphorus, and the simultaneous production of a silicon compound that is volatile at the temperature employed. There is the further object of incorporating in the mixture such elements as will permit the ready disintegration of the furnace product, when treated with water, thereby avoiding the necessity of expensive and difficult fine grinding.

For these purposes the inventor uses carbon and calcium fluoride, which, when fused with monazite sand in an electric furnace, will reduce and volatilize the phosphorus and form silicon tetrafluoride which also is volatile. Further, the furnace mixture can be so compounded with lime that the production of calcium carbide will be formed throughout the mass, and when the latter is treated with water it disintegrates, yielding a product finely divided and not requiring expensive grinding. The furnace charge may be compounded thus:

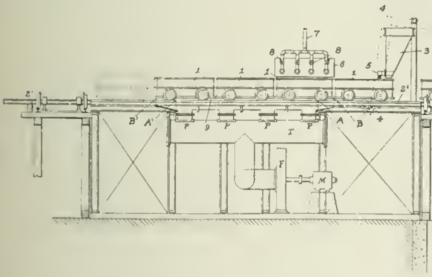

FIG. 3—SINTERING MACHINE

| | Pounds |
|---|---|
| Monazite sand | 1.0 |
| Carbon (petroleum coke) | 1.1 |
| Quick-lime | 0.8 |
| Calcium fluoride | 0.15 |

Various types of electric furnace have been used in producing the thoria, and both direct and alternating current can be employed of different voltages and amperages. The inventor prefers, however, to use a crucible furnace, also alternating current varying in amperage from 100 to 300 amperes and in voltage from 25 to 60 volts.

After the furnace product has been disintegrated by water, the lime is removed by decantation, and the residue is treated with acid to obtain a solution from which thoria can be extracted. (1,087,099, Feb. 17, 1914.)

### Ore-Sintering Apparatus

**A form of apparatus** for sintering finely divided ores and similar materials, recently patented by Mr. **Albert F. Plock**, of Pittsburgh, Pa., is shown diagrammatically in Fig. 3. In general, the process bears similarity to that of Dwight & Lloyd, wherein a comparatively thin bed of material is ignited and sintered while being passed over a receptacle from which air is being exhausted, thereby forcing a down draft through the bed of ore. Referring to the figure, cars 1, equipped with herringbone grates, receive a charge of material from the hopper 3, pass under the igniter 6, and across the air tank T. A motor M operates a fan F which exhausts the tank T, and thereby draws a current of air downward through the ore bed on the cars. The apparatus is designed to permit either continuous or intermittent operation, in accordance with the character and requirements of the charge; to permit the removal of the ore-carrying units to any distance from the sintering machine and to provide units which can be handled in any special manner desired. Each car has its own separate air chamber 14, as shown in Fig. 4 which illustrates a vertical cross section of the apparatus through the ignition hood. Fig. 2 also shows the manner of connecting the air chamber of the car with the chamber T that connects with the exhaust fan. This form of connection may be modified by placing it at one side of the car, or it may lead from the bottom of the car outside the wheels instead of between them. (1,089,153, Mar. 3. 1914.)

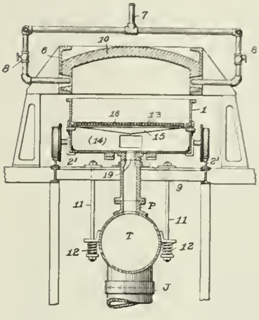

FIG. 4—SINTERING MACHINE

**Another form of sintering apparatus** is that of Mr. John E. Greenawalt, of Denver, Col., shown in Fig. 5. It consists, in brief, of a sintering pan 1 adapted to turn on hollow trunnions 5. It is provided with a grate G on which a charge of ore is placed. The ignition apparatus is run over the pan, and the ignition of the charge is effected from two burners B of special construction. The ignition apparatus consists of a

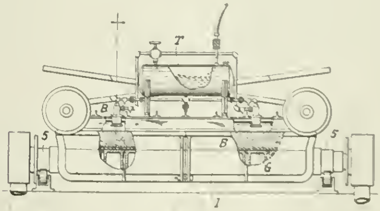

FIG. 5—SINTERING APPARATUS

tank T of oil fuel, with suitable connections to a source of compressed air, on the one hand, and with the burners on the other. The roof of the ignition hood is perforated to permit a down-draft current of air to be drawn into a combustion chamber, through the ore and out by way of the trunnions. In such an apparatus, the uniform ignition of the areal surface of the charge is an important point, and in order to provide for this, a special form of burner is used, shown in Fig. 6, by means of which a horizontal blanket of flame is projected over the entire surface of ore. The burner consists of two parts, *a* and *b*, bolted together. Between the two parts is placed a metal disk with radial slots, as shown at S. Oil is injected through a Schutte-Koerting spray-nozzle 24, and air enters tangentially at 25. The mixture strikes the cone 19 and is diverted horizontally through the radial slots of the metal disk, and spreads equally over the surface of the charge, forming a sheet of inflammable particles which, when ignited, produces a blanket of flame igniting instantaneously the entire surface of the charge. The projection of the horizontal streams of fuel is under sufficient head to suffer no material deflection by the downdraft current of air passing through the charge. (1,088,818, Mar. 3, 1914.)

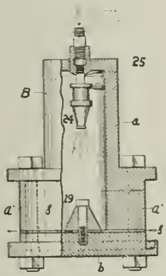

FIG. 6—BURNER FOR SINTERING APPARATUS

### Briquetting

**The preliminary treatment** of mineral and metallic substances which are to be united by pressure is the subject of a patent granted to **Arpad Ronay**, of Berlin, Germany. "The essential feature of this invention is that hot steam shall be introduced into the mass of particles to be pressed, at that period of time which precedes the pressing operation." The process may be applied to the briquetting of flue dust, ores, coal dust, metal filings or shavings and combination of such materials. The use of steam permits the displacement of air in the mass, and also introduces a small quantity of water which is of advantage. The desirable oxidation of the particles is brought about uniformly and quickly at the high temperature of the operation.

It is essential that steam, as such, exists in the mass at the time of briquetting. (1,087,183, Feb. 17, 1914.)

## Synopsis of Recent Chemical and Metallurgical Literature

### The Work of Crushing

In a mathematical discussion of the work done in crushing rock and ore, and the methods of finding the mechanical efficiencies of crushing machines, Mr. **Arthur F. Taggart** concludes that Kick's law is correct and that the so-called law of Rittinger is inapplicable.

The discussion appears in the January issue of the "Bulletin" of the American Institute of Mining Engineers. According to the author the reason why different investigators have arrived at different conclusions regarding the power consumed in crushing and the efficiencies of different machines, is that the tests are based on different assumptions. Some assume the correctness of Rittinger's law, that the work of crushing is proportional to the reduction in diameter or to the new area produced, while others base their work on Kick's law, which states that the work of crushing is proportional to the volumes produced. After analyzing the proofs of various experimenters, the author comes to the conclusion that Kick's law is correct wthin the limits of experimental error.

"Attempts to prove the work of crushing proportional to the reduction in diameter err in one of the following ways:

"1. By neglecting the distance quantity in the work formula.

"2. By assuming that particles in a crushing machine are acted upon in such a way as to produce simple shearing stresses.

"3. By assuming that the force exerted is a constant.

"4. By confusing 'force' and 'work.'

"The difference in the results obtained according to the two assumptions is small throughout a considerable range of sizes. The difference is marked in the fine sizes, where the greatest amount of power is wasted."

**Tin Concentration at the Geevor Mill, Cornwall.**—The Cornish practice in tin dressing has frequently come in for more or less criticism from those who consider the methods inefficient and not in accord with modern ideas. On the other hand Cornish operators are likely to feel that much of the criticism comes from men unfamiliar with local conditions, and therefore unqualified to speak with authority. *Bulletin No.* 110, Inst. of Min. & Met., contains the record of an application of modern ideas of ore dressing at the Geevor tin mill, written by Mr. Horace G. Nichols. *Bulletin No.* 111 contains the extended discussion aroused by Mr. Nichols' paper.

It appears that the Geevor mill was remodeled under the technical direction and responsiblity of Mr. R. Gilman Brown, and that Mr. Nichols was Mr. Brown's representative in the matter of starting the mill and gathering technical results. Unfortunately, and for reasons that do not appear fully in the discussion, the remodeled mill was unsatisfactory to the directors of the company, and it was changed back to conform with the method adopted at Dolcoath. This led Mr. Nichols to make public record of the performance of the remodeled mill in order to justify the methods adopted as compared with those in vogue before the change.

The principal feature of the remodeled mill is an attempt to introduce the principles of stage crushing, classification and concentration; adapting the crushing to the requirements of the ore, removing coarse mineral as soon as possible, and regrinding only such parts of the pulp as needed further treatment. The introduction of the Hardinge mill, Richards-Janney classifier and Deister table were "modern" features of the new mill. The use of vanners as coarse concentrators will appear strange and unusual to some, but these machines were in the old mill, and it was desired to use them as far as possible. The difficulty of remodeling an old mill to conform exactly with one's ideas will be readily appreciated by all engineers.

Mr. Nichols states that the recovery under the old practice was only about 40 per cent, and that the tailing contained 19 lb. "black tin" (about 2/3 metal) per ton. He admitted that a higher recovery, possibly 60 per cent, could be made under former conditions, but only by production of a low-grade concentrate. With the new system of treatment the yield was over 75 per cent.

The final treatment, arrived at by much testing, was as follows: From the stamps, which delivered a pulp containing about 35 per cent + 80 mesh material, the ore flowed to a 3-compartment Richards-Janney classifier. The first spigot product, representing +80 mesh pulp, flowed to a Hardinge mill for regrinding; the second and third spigot products were treated on two sets of vanners, three machines in each set. The first set of vanners had a belt travel of 3 ft. per min., and were dropped 5¼ in. at the tail end; the second set had a belt speed of 2½ ft. per min., and a tail drop of 4½ in. The overflow from the classifier was thickened in Callow cones, the thick product being treated on vanners which were run as nearly level as possible and speeded so as to obtain a not too clean concentrate. The tailings from the first two sets of vanners were reground in grinding pans and combined with the tailing from the third set. This pulp was then again classified in a 2-compartment classifier and concentrated on Deister tables. The finest pulp was ultimately thickened and treated on Deister slime concentrators.

The feed to the tube mill contained 62 per cent solids. This thick feed was regarded by the author as an essential requirement for regrinding tin ore. In concentrating with and without the use of a tube mill for regrinding a part of the ore, in the latter case depending on the stamps to grind the whole product fine enough, the percentages of extraction were respectively 78.5 and 69.5. Cone dewaterers were used over grinding pans, thereby eliminating much water and pulp finer than 120 mesh, and increasing the solids in the pan feed from 23 per cent. to 42 per cent. The author concludes from the results obtained that the principles of concentration adopted in treating other ores are equally applicable in tin ores.

### Gold and Silver

**The Cyanide Process.**—A chemical and historical review of the metallurgical process which to-day holds first place as a means of recovering gold and silver from their ores is given by Mr. C. A. Mulholland in the Australian Mining Standard, Jan. 8, 15 and 22, 1914. Concerning the theory of the dissolution of gold in a cyanide solution, the author affirms that gold goes into solution in an indirect fashion, to form gold-potassium cyanide.

"Chemical energy is electrical energy. This dissolution of metals and their compounds and all reactions in solution take place by an interchange of electrical charges which are inherent in all kinds of matter. In a solution whose equilibrium is balanced the atoms and molecules with their definite electrical charges are also in equilibrium. Atoms or molecules going into solution—becoming ions—receive an electrical charge or become ionized, and as soon as they are caused to give up their charges they cease to be ions and separate out of the solution in the neutral or molecular state. In order that a metal can enter into solution it must be capable of withdrawing the charges for its own ions from those of others—for instance, from hydrogen or other metallic ions already present in the solution and the ion from which a charge has been taken separates in the neutral state. Applying this to the particular case of gold entering into a solution of cyanide its modus solvendi may be briefly described as follows:

"The electrolytic pressure of gold in presence of a cyanide solution (that is the difference between its solution pressure and the osmotic pressure of the ions in solution) is just sufficient to enable it to take up an ionising charge of low value from the potassium ions in solution to form an aurous ion which unites with hydroxyl to form a hydrate or more probably hydrated peroxide, which is readily soluble in potassium cyanide.

"The efficient initial cause of the dissolution of gold in a cyanide solution appears to be an electrochemical one, involving, primarily, the elements gold and oxygen. The slight apparent solubility of gold in cyanogen, cyanogen bromide and similar compounds is due to a similar cause and not to the nascent cyanogen molecule."

Another important contributing cause is the phenomenon of catalysis. Among catalytic substances acting in the cyanide process are the silica and ferric oxide invariably associated with the ore under treatment.

A third contributing cause of dissolution is the state of dilution of the solution. When the dissociation of potassium cyanide in any solution has the greatest concentration of ions in unit volume, this point corresponds, within certain limits, with the solvent power of the solution.

"A fourth contributing cause is the property possessed by potassium cyanide of dissolving with tne absorption of heat, so that the dissociation presure increases with the increae of temperature, within certain limits. This property influences the whole process by which substances enter the solution and determines their order and the direction of displacement of the equilibrium of the reacting bodies, however numerous they may be. The temperature, therefore, of the cyanide solution is another contributing factor in the dissolution of gold and other metals."

The author applies these considerations to the reactions occurring in the cyanide and bromocyanide processes, and concludes with a historical review of the patents.

---

## Notes on Chemistry and Metallurgy in Great Britain

*(From Our Special Correspondent.)*

### Rail Steels for Electric Railways

At a meeting of the Institution of Civil Engineers on February 24th Mr. **Wm. Willox** read a paper in which he described the results of tests which he had made bearing on the reduction of the life of rails in tunnels from an average of about five years to an average of rather less than three years, and in some places below one year, on the electrified section of the Metropolitan Railway.

The tests were mainly confined to the curve between Aldersgate and Farringdon Street, and were made with a great variety of steel rails. The traffic at this particular part of the line is exceptionally heavy and at busy times in the morning and evening there are more than 40 trains running in the hour on one line.

The author's investigation has been of an extensive character, and included chemical analyses, tensile tests, tup tests, and impressions of all the rails experimented upon as well as the etching of a large number of sections of the rails. In addition to the results of these tests the results obtained with various steels, including manganese steel, for actual wear at points and crossings are given.

The author points out the necessity for railways keeping their expenditure on permanent ways within a reasonable figure, especially when only about three hours can be devoted to the work of putting down fresh rails, which must necessarily be done after midnight and before the resumption of traffic in the morning.

In giving the good results obtained with manganese steel points and crossings on the curve mentioned, the author points out that, as far as he knows, the use of manganese steel in England, even at crossings, has hitherto been very restricted, and that therefore these results may possess some value. Summing up the results obtained the author has arrived at the conclusion that the rails which have proved the best and most economical are of high-silicon steel manufactured under careful supervision by the process introduced by the late Mr. C. P. Sandberg from basic open-hearth, basic Bessemer and acid Bessemer steels.

### The Effect of Alternating Currents on Primary Cells

At the mid-February meeting of the Royal Society Mr. **S. G. Brown** presented a very interesting paper on the effects produced by the passage of alternating currents of various frequencies up to a maximum of 20,000 through simple voltaic cells. The passage of an alternating current through any such cell appears to prevent entirely polarization, and as a consequence the chemical action becomes very much greater, and therefore the cells yield a much greater quantity of continuous current than they would normally supply.

When the surface of the zinc anode is relatively small the passage of an alternating current stimulates the chemical action between the electrolyte and the anode, and this causes a considerable increase in the current given out. Such increase is dependent in extent on the density of the alternating current, and the experiments described by the author go to show, if not to prove, that when the density is great enough the chemical action may be so intensified as to cause oxidation of any known metal used as the anode.

### The Carbonization of Coal

Dr. **John Harger** recently read a paper before the Liverpool section of the Society of Chemical Industry in which he dealt with the chemical nature of coal and the products of its carbonization.

He said that the researches of many able workers for about a century had not resulted in the acquisition of any definite knowledge of the chemical composition of the substances of which coal was composed, and that with regard to 98 per cent of its constituents it was only possible to guess at their chemical composition. Some coals yielded 40 per cent of soluble matter to pyridine, and although part of this dissolved substance was soluble in chloroform yet it cannot be directly obtained from coal by treatment with chloroform; and this went to show that that portion of the pyridine extract which was soluble in chloroform did not exist in that form in the coal itself, but was formed by the action of the pyridine on some original constituent of the coal.

The government chemists as Eskmeals considered that the inflammability of any given coal is determined by the proportion soluble in pyridine, but he considered that that view was open to question.

The author reviewed the controversy between Dr. Wheeler and Professor Lewes concerning the processes of decomposition which occur when coal is heated, and he supported Professor Lewes in the view that the decomposition at the higher temperatures consists in a splitting up of pitch-like matters formed earlier at a lower temperature. In support of this he showed that at a temperature of about 270 degs. C. ordinary bituminous coal underwent a change not readily noticeable.

With regard to gas-works practice the author considered that modern methods should be revised, because he was of opinion that the existing practice of high temperature distillation is more suitable for the conditions of bygone times, and that the old method of working at lower temperatures was more suitable to modern requirements, such as a yield of light petroleum and smokeless fuel for ordinary consumption.

### Rail Corrugation

At the meeting of the Institution of Civil Engineers on the 24th of February Mr. **S. P. W. D. Sellon** read a paper on "Rail Corrugation and its Causes."

He came to the conclusion that the "crests" are simply cold-rolled whilst the surfaces in the hollows are crushed by vertical loads, consequent on the oscillations of the wheels, above the elastic compressive limit of the steel; but he did not discuss the cause of the oscillatory character of the load. At ordinary speeds the pitch of the corrugations on tram rails corresponds with a frequency of about 100 per second.

The author was quite confident as to the means of prevention afforded by hard steel. He said that between 1898 and 1903 he was responsible for the purchase of 10,000 tons of tram rails with a specified carbon content of not less than 0.6 per cent which had been laid in various towns in England and had not exhibited any corrugation; but where the same tramways had been extended with rails complying with the British standard specifications and containing from 0.4 to 0.55 per cent. carbon corrugation had occurred on such extensions with the same rolling stock and the same method of construction.

### Market Prices

February, 1914.

| | £ s. d. |
|---|---|
| Aluminium ingots, ton lots | 86. 0. 0 |
| Alum, lump loose, ton | 5.10. 0 |
| Antimony, Star Regulus, ton | 28. 0. 0 |
| Borax, British refined crystal, cwt | 18. 6 |
| Copper Sulphate, ton | 22.10. 0 |
| Caustic Soda, 70%, ton | 10. 5. 0 |
| Copper Ore, 10 to 25%, unit | 11/3 to 11. 9 |
| Ebonite Rod, lb. | 4. 6 |
| Hydrochloric acid, cwt | 5. 0 |
| India-rubber, Para, fine, lb. | 3. 0 |
| Mica, in original cases, medium | 3/6 to 6. 0 |
| Petroleum, Russian spot, gal. | 9¼ |
| Quicksilver (Spanish), bottle | 7.10. 0 |
| Sal-Ammoniac, cwt | 2. 2. 0 |
| Sulphate of Ammonia, ton | 12.12. 6 |
| Sulphur, recovered, ton | 5.10. 0 |
| Shellac, cwt. | 3.14. 0 |
| Platinum, oz., nominal | 9. 5. 0 |
| Tin Ore, 70%, ton | 113 to 115. 0. 0 |
| Zinc, Vielle, Montagne | 25.12. 6 |

### Differences

| *Higher* | | *Lower* | |
|---|---|---|---|
| Copper ore, unit | 3 | Aluminium (ton) | 4. 0. 0 |
| Sulphate of Ammonia (ton) | 2. 6 | India Rubber (lb.) | 2½ |
| Tin Ore, ton | 10. 0. 0 | Shellac, cwt. | 8. 0 |
| Zinc, ton | 12. 6 | Copper, ton | 1.12. 6 |
| | | Tin, ton | 4.10. 0 |
| | | Lead, ton | 10. 0 |

Copper opened £66, was £66.17.6 on the 4th, then declined to £65 on the 9th. It was a little higher on the 10th and 11th but again reached £65 on the 13th, and, after a slight recovery, £64.10.0 on the 18th, and has held about that price, closing at £64.7.6.

Tin opened £182 and rose till £187.10.0. was reached on the 4th: it then fell off, being £185 1/8 on the 9th, and £183.12.6 on the 12th; £183 on the 16th and £181 on the 17th, with fluctuations, the tendency has been generally lower, showing £175.15.0 on the 23rd and closes £175.10.0.

**Haematite** opened 61/- and has not varied throughout the month, closing the same.

**Scotch Pig** opened 56/, and was up to 57/9 by the 5th, keeping fairly strong till the 16th, when it was 57/: on the 17th, 18th and 23rd it was 56/9 and closes 56/6.

**Cleveland** opened 50/7½ and rose, reaching 51/9 by the 5th, and was fairly strong till the 13th, when it was 51/1½: it has since had a lower tendency, being 50/9 on the 18th and 23rd, and closes 50/6.

Lead opened £19.10.0, and rose to £20.10.0 on the 3rd: by the 9th it had fallen to £19.15.0 and remained there till the 11th, when £19.17.6 was reached, which has been maintained, closing price being £20.

# Coal-Gas Plant and Lime Plant at the Niagara Works of the American Cyanamid Company

The production of calcium cyanamid represents one solution of the problem of the fixation of atmospheric nitrogen, that is, of the problem to transform the inert and useless elemental nitrogen in atmospheric air into some useful compound.

The calcium cyanamid industry is the result of the experiments of Drs. Frank and Caro, who wanted to produce calcium cyanid from calcium carbide and nitrogen by a reaction analogous to that by which barium cyanid is formed from barium carbide and nitrogen. Their experiments showed, however, that in the cost of calcium the reaction is a different one since the calcium cyanamid instead of cyanid is formed. The inventors, however, found at the same time that the calcium cyanamid—which they had not originally intended to produce—was nevertheless a very valuable product as it can be used almost directly in the form produced as a fertilizer and may also be employed as a starting material for the production of other chemicals.

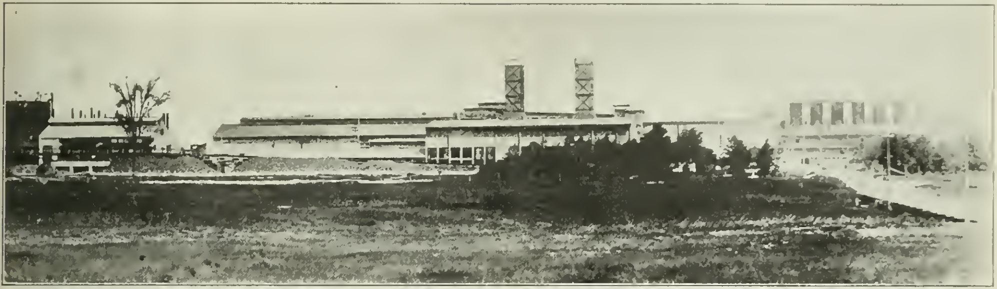

FIG. 1—AMERICAN CYANAMID COMPANY'S WORKS AT NIAGARA FALLS
(Lime plant at the extreme right and coal gas plant at the extreme left)

In the last ten years the production of calcium cyanamid has become a big industry. Its history has been given in the columns of this journal. Reference may be had to former articles published in our volume I, page 423; vol. II, p. 204; vol. III, p. 28, 79, 117; vol. IV, p. 136, 188, 327; vol. V, p. 59, 72, 77, 98, 198, 289, 374, 464, 465, 479; Vol. VI, p. 139, 339, 341, 506; Vol. VII, p. 212, 305, 309, 360; vol. VIII, p. 47, 287, 539, 548, 589, 617, 682, 692; vol. IX, p. 12, 21, 100, 123, 476, 545; vol. X, p. 550, 551, 667; vol. XI, p. 438, 476.

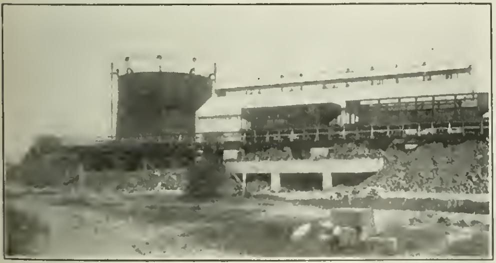

FIG. 2—RETORT HOUSE AND COAL-HANDLING ARRANGEMENT FOR THE RETORT HOUSE

In the last ten years cyanamid factories have been established all over the world. One of the largest is located at Niagara Falls, Ont., Canada, where electric power can be obtained at a sufficiently low rate.

The American Cyanamid Company owns the sole right to manufacture and sell cyanamid in America. Its factories at Niagara Falls began operations on January 1st, 1910. The original output was 12,000 tons a year, but this was increased during 1912 to approximately 32,000 tons a year, and further extensions are under way to give a yearly output of 64,000 tons.

From the very commencement of operations at Niagara Falls it was clear that a plant capable of producing 12,000 tons per year was totally unable to meet the market requirements, but the directors of the American Cyanamid Company adopted the policy that they would thoroughly prove the commercial practicability of and demand for cyanamid before building a large plant. After two years' experience they realized that the product could be looked upon as an undoubted commercial success. Methods of manufacture have been simplified and cheapened, and it is now necessary to double the existing plant in order to cope with the increasing orders.

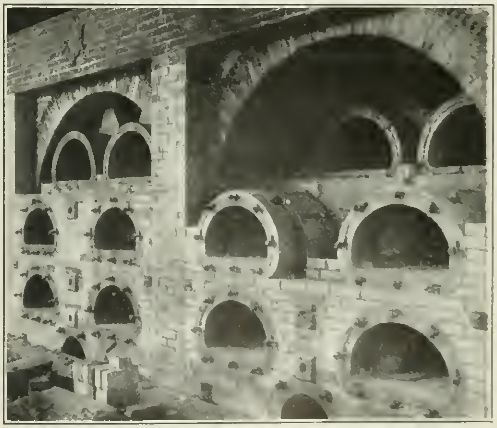

FIG. 3—MANNER OF LAYING UP THE SECTIONAL SILICA RETORTS AND SETTINGS

Cyanamid is a bluish-black, odorless, powdered material. It contains from 18 to 20 per cent ammonia, about 12 per cent carbon, or lamp-black, and the equivalent of about 70 pounds of slaked lime. The material is shipped in burlap bags and can be stored indefinitely.

Cyanamid nitrogen is readily soluble. Ninety-six per cent will dissolve out in cold water and is, therefore, available as plant food. On contact with the soil it reacts quickly and changes finally into the form of double ammonium compounds.

Every 100 pounds of cyanamid contains the equivalent of about 70 pounds of slaked lime which adds considerably to its value as a fertilizer. This lime costs the farmer nothing, as cyanamid is sold on the basis of the ammonia it contains as determined by analysis.

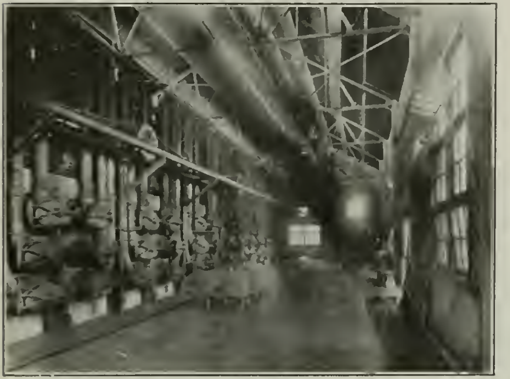

FIG. 4—CHARGING FLOOR OF RETORT HOUSE WITH CONVEYOR SYSTEM AND COAL BUGGY

### Starting Materials of Cyanamid Manufacture

Since calcium cyanamid is produced by the reaction of nitrogen gas with hot calcium carbide, and since calcium carbide is made in the electric furnace from lime and coke, the principal requirements of cyanamid manufacture are, besides cheap electric power, lime, coke, and nitrogen gas.

It should be emphasized that the nitrogen gas before being used must be separated from the oxygen gas with which it is mixed in atmospheric air. In some of the European cyanamid factories this is done by liquefying the atmospheric air and then separating the oxygen from the nitrogen by fractional distillation. At Niagara Falls another purely chemical and very simple method is employed. The atmospheric air is passed through a hot copper sponge whereby the oxygen in the air combines with the copper and leaves practically pure nitrogen. The copper oxide is then reduced again to copper sponges in a second stage by means of coal gas as reducing agent. The reduced copper sponge reacts again with atmaspheric air and produces nitrogen and so on. The copper sponge, therefore, undergoes cyclic oxidations and reductions.

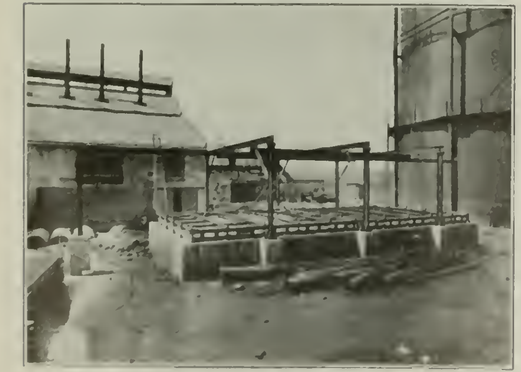

FIG. 5—PURIFYING BOXES

The nitrogen ovens consist of a series of vertical retorts heated by small individual furnaces. Copper sponge is placed in these retorts, and when the retorts are brought to the proper temperature air is forced through the retorts and the oxygen of the air combines with the copper as cupric oxide, leaving the nitrogen free. This is the first stage. In the second stage the air is then shut off and coal gas is passed through the retort, which reduces the copper oxide to metallic copper. The nitrogen produced in the first stage is forced through pipes into the electric furnaces where it combines with the calcium carbide and forms calcium cyanamid, or commercial cyanamid.

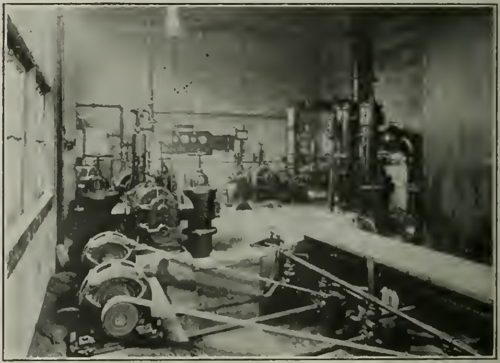

FIG. 6—MACHINERY ROOM WITH DOHERTY WASHER COOLER AND CENTRIFUGAL PUMP

### Coal Gas Plant

Since coal gas is used for the reduction of the copper oxide (in the production of the nitrogen gas) and since coke is used for the manufacture of the calcium carbide, a coal-gas plant is an important part of the factory, the coke going into the carbide factory and the coal gas into the cyanamid factory proper.

The coal-gas plant was designed and installed by the Improved Equipment Company of New York City, and has a capacity of approximately 500,000 cubic feet per twenty-four hours. There are seven benches of sizes equipped with the Doherty bench fuel economizer and sectional silica retorts and settings.

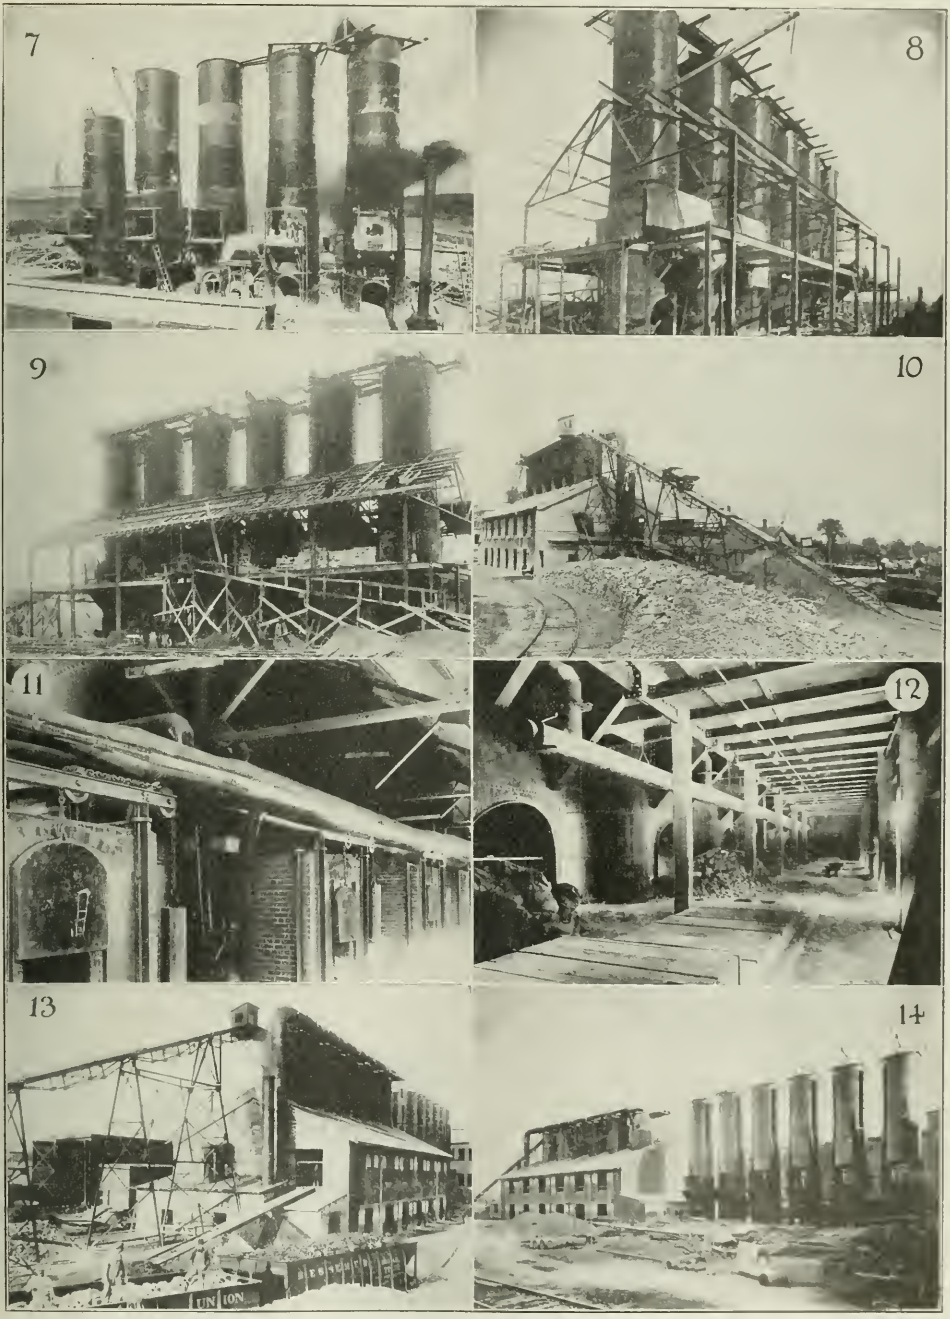
The accompanying illustrations give an idea of the principal features of this installation. The size of the whole plant can be seen in Fig. 1, with the lime plant at the extreme right and the coal gas plant at the extreme left.

Fig. 2 shows the retort house and holder and coal handling arrangements for the retort house.

Photographs were taken during the course of the installation of the plant, showing various stages in construction. Fig. 3, which shows the manner of laying up the sectional silica retorts and settings, should be of particular interest to gas men.

The view of the charging floor of the retort house (Fig. 4) shows the coke conveyor system and coal buggy.

The purifying boxes (Fig. 5) are of the concrete outdoor type. This view also shows the cooling coils of the Doherty washer cooler on the outside of the retort



FIGS. 7 TO 14—LIME PLANT IN COURSE OF CONSTRUCTION

Fig. 7—Kiln shells erected and fire-clay lining started; Fig. 8—kiln shells completed and section of waste gas piping installed; Fig. 9—work started on the roof of the lime-kiln building; Fig. 10—complete lime plant; Fig. 11—furnace or firing floor with piping for Eldred process and counterweight arrangement of the charging doors; Fig. 12—lime discharge floor. Fig. 13—old plant with new additions; Fig. 14—old plant with new additions.

house as well as the position of the holder which has a capacity of 100,000 cubic feet. This holder is only used as a relief holder when the nitrogen ovens do not use the output of the benches.

One of the interesting features of this installation has been the flexibility of the benches in that as a larger output is required the heats are raised and benches forced to meet the demand, or the heats are lowered when for some reason the nitrogen ovens are shut down or are not running to full capacity.

The view of the machinery room (Fig. 6) shows the Doherty washer cooler with centrifugal pumps for its operation.

### Lime Plant

For the manufacture of the calcium carbide which represents the first step in cyanamid manufacture, coke and lime are required. The coke comes from the coal-gas plant which is described.

The lime plant for the production of lime was also designed and installed by the Improved Equipment Company, and the original plant consisted of six Doherty-Eldred lime kilns equipped with the Eldred process and induced draft.

Figs. 7 to 9 show this plant in course of construction. In Fig. 7 the kiln shells are being erected and the fire clay lining started; in Fig. 8 the kiln shells are completed and section of waste gas piping installed, and in Fig. 9 work is started on the roof of the lime-kiln buildings.

The complete plant is shown in Fig. 10 with the incline for conveying the limestone to the top of the kiln.

Fig. 11 shows the furnace or firing floor, showing the piping for the Eldred process and the counterweight arrangement of the charging doors, and the view of the lime discharge floor in Fig. 12 shows the arrangement for handling lime and the holes for the conveyor in the floor.

At the present time the lime plant is being doubled in size. Figs. 13 and 14 show the new addition as well as the old plant.

---

**The New Heat Treating Department** of the Ingersoll-Rand Company's plant at Phillipsburg, N. J., which was installed by Tate-Jones & Co., Inc., of Pittsburgh, is now completed and in successful operation. The plant at Phillipsburg handles a large output of drills and compressors and the furnace equipment in this department consisted of two large double-chamber annealing furnaces, two semi-muffle furnaces for pre-heating, six lead and two solution baths for hardening and three oil baths for tempering. All of these furnaces are fired with fuel oil which this plant has been using with great success since changing from gasoline gas in January of last year. The complete installation of furnaces, burners and pumping systems was made by the Tate-Jones Company and they now have in the two heat-treating departments at Phillipsburg forty-three and in the blacksmith shop four Tate-Jones furnaces.

**Palace of Machinery at the Panama-Pacific Exposition.**—If confirmation is needed of the often-repeated press assertion that the San Francisco World's Exposition will open complete on time on February 20, 1915, it seems to be found in the present finished condition of the Palace of Machinery. It covers a floor space of about eight acres; water, gas, electricity, compressed air, steam, overhead crane service are all provided in systematic and comprehensive detail. The installation of heavy machinery should begin at an early date and shipments which reach the exposition by July 1, 1914, may be expected to be immediately put in place.

## New Metallurgical Laboratory in California

The new ore-testing laboratory of Mr. Charles Butters, at Oakland, Cal., is particularly designed for investigations in the treatment of refractory ores. Facilities have been provided for tests on any scale up to four or five tons, and suitable treatment can be determined for gold, silver or copper ores by any of the leaching processes in general use.

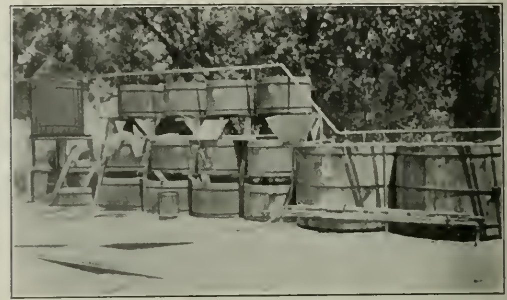


FIG. 1—LEACHING TANKS, BUTTERS' METALLURGICAL LABORATORY

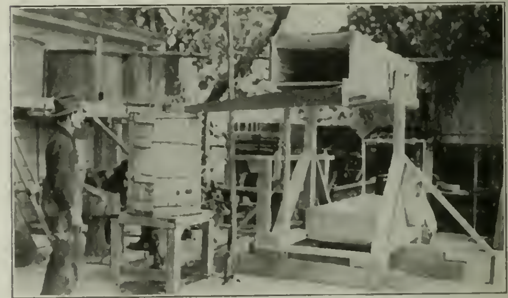

FIG. 2—VIEW OF BUTTERS' FILTER IN HORIZONTAL POSITION

The crushing appliances, which are all run by electric power, comprise two Grusonwerk ball mills, Gates gyratory crusher, Blake crusher, sample grinder and tube mills.

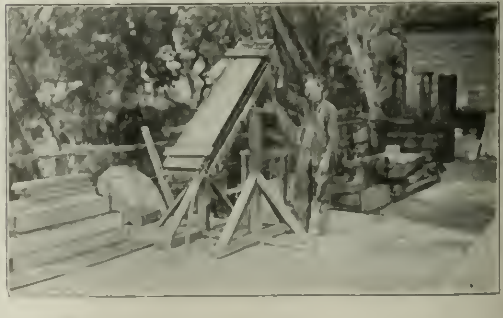

FIG. 3—FILTER IN INCLINED POSITION FOR DISCHARGING

Leaching and agitation tanks of various sizes have been erected. A general view of the leaching plant is given in Fig. 1. The agitation tanks comprise the regular mechanical type, Pachuca type and a form in which mechanical stirrers are combined with air-lifts.

The new type of Butters filter is shown in different views, Figs. 2 to 4. The details of this filter have been worked out at the testing laboratory. Fig. 2 shows the device in its horizontal position, ready to receive a charge of ore pulp. The apparatus consists of a number of superposed trays, each containing a filter mat of the regular type. These are charged simultaneously from a manifold that delivers pulp at one end of the apparatus. Fig. 3 shows the filter in an inclined position, ready to discharge. In Fig. 4 it is shown in the vertical position as it appears when the cake has been discharged.

Concentration tests can be made on the model Wilfley table shown in Fig. 4.

A zinc box of large capacity is provided for the recovery of valuable metals from cyanide solutions, and other systems of precipitation can be installed when necessary.

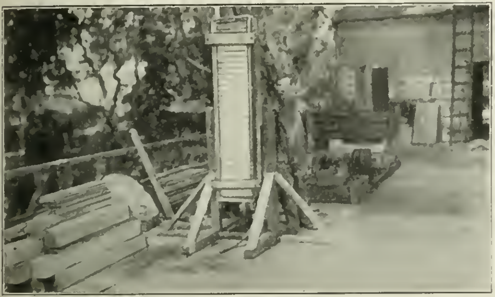

FIG. 4—FILTER IN VERTICAL POSITION, CAKE DISCHARGED

In addition to the experimental laboratory there is a well equipped assay office and analytical laboratory, the rooms used for this purpose being large and exceptionally well lighted, and furnished with every necessary appliance.

The entire installation is situated on the grounds of "Roselawn," Mr. Butters' Oakland residence. It is accessible both from Fifty-ninth Street and from Shafter Avenue, where the Oakland, Antioch and Eastern Railway affords a ready means of delivery. Rockridge station on this line immediately adjoins the plant.

---

**The Goldfield Consolidated Mines Co.** has declared a regular dividend of thirty cents per share, which will be payable on April 30 to stockholders of record on March 31.

**Butte & Duluth copper costs** for February are announced as $8\frac{1}{2}$ cents per pound. The company is treating oxidized copper ore by leaching and electrolytic precipitation. The ore averages 2.11 per cent copper. The cost per ton of ore was: Sulphuric acid, \$0.72; electric power, \$0.375; mining and transportation, \$0.23; fuel, \$0.14; labor, \$1.029; total, \$2.494.

**The Arizona Copper Co., Ltd.,** produced 1531 tons of copper during the month of February, 1914.

**A short course in coal mining** is announced by the Colorado School of Mines for the benefit of coal mine employees. The course lasts eight weeks, from April 1 to May 27. Elementary chemistry, geology, mathematics, mining, mechanics and drawing will be offered. There will be no fee for instruction. Small laboratory fees will be required. The course will aid candidates for positions under state civil service.

## Some Interesting Oil Tests

Even to-day, one frequently hears engineers speak of oil "wearing out," some even going so far as to maintain that after oil has been in use for a certain length of time it should be discarded and replaced by new oil.

In order to determine exactly what deterioration oil suffered when in constant use, the Richardson-Phenix Company recently had a rather elaborate series of tests made on different samples of oil at the laboratories of Cornell University.

These tests proved conclusively that if oil is properly filtered it can be used over and over again indefinitely without losing any of its lubricating qualities. To show the value of the information obtained in these investigations, the data secured from the Hotel McAlpin tests has been selected as representing the most severe operating conditions.

The power plant of the Hotel McAlpin, New York City, is equipped with a Richardson central oiling and filtering system, supplying flooded lubrication to four Wetherill engines having forty-eight points of lubrication, two Clayton air compressors having six points of lubrication, two Laidlaw-Dunn-Gordon compressors having sixteen points of lubrication and one Wetherill crank-and-flywheel pump having thirty-two points of lubrication, making a grand total of 134 points of lubrication supplied by the system.

This plant operates twenty-hours per day, 365 days per year, and the average temperature in the engine room is 100 deg. Fahr. On account of the great variety of machines lubricated, the high load factor and the exceptional temperature conditions, the work imposed on this lubricating system is probably as severe as can be found in any power plant. The oil is a good grade of mineral oil, known as "extra brand engine oil."

To find out exactly how much oil was circulated through the oiling system, ten tests were made at the power plant and it was found that the *average* amount of oil handled by the lubricating system was 150 gal. per hour, or 3600 gal. of oil per day. This is an equivalent of 1800 bbl. per month. It is interesting to note that although this enormous amount of oil is supplied continuously to the bearings, it is only necessary for this plant to add to the system 3 bbl. of oil per month, but even these 3 bbl. cannot be charged to natural shrinkage in the system, for large quantities of oil are drawn off from the filters and used in cans for hand-oiling of small pumps, valve gears and other bearings not connected to the oiling system. But even charging 3 bbl. against the system it is evident that this plant pays for less than two-tenths of 1 per cent of the oil used for lubrication.

To determine the changes undergone by the oil, a sample of the new oil as received in barrels from the manufacturers was secured and also a sample of the oil drawn off from the clean-oil compartment of the filter. These samples were sealed in the engine room and shipped to the testing department at Cornell University, where without any further purification or filtration, a series of tests were made under the supervision of Professors Carpenter and Sawdon. The results of these tests are given in the accompanying tables and curves. They prove that a modern oiling system is without doubt one of the best investments that can be made in any power plant.

A series of friction tests were made on a Thurston railroad lubricant tester, having a hardened steel journal and bronze bearings with a total area of 20 sq. in. In all tests the testing machine was run at a constant speed of about 360 r.p.m. and the load applied in increments of 1500 lb. total pressure of 75 lb. per square inch. The test at each load was continued until the friction and temperature of the bearings had become constant. The oil was fed upon the side of the bearing through a sight-feed oiler and the feed maintained as nearly constant as possible throughout all the tests. Readings were made at ten-minute intervals and a large amount of interesting data secured. The summary of these tests is shown in the following tables:

SAMPLE "A"—NEW OIL

| | | | | | |
|---|---|---|---|---|---|
| Press. on bearing, total lbs. | 1500 | 3000 | 4500 | 6000 | 7500 |

| Minimum coeff. of friction | .01166 | .00666 | .00533 | .00458 | .00373 |

SAMPLE "B"—PURIFIED OIL FROM RICHARDSON FILTER

| | | | | | |
|---|---|---|---|---|---|
| Press. on bearing, total lbs. | 1500 | 3000 | 4500 | 6000 | 7500 |
| Press. on bearing, lbs per sq. in. | 75 | 150 | 225 | 300 | 375 |
| Duration of test, mins.... | 150 | 60 | 60 | 80 | 50 |
| Temperature of bearing, max. | 120.0 | 125.5 | 132.5 | 144.5 | 147.2 |
| Temperature of room, aver. | 74.0 | 74.8 | 75.3 | 77.0 | 77.5 |
| Diff. in temp. bearing and room | 46.0 | 50.7 | 57.2 | 67.5 | 69.7 |
| Rate of feed, drops per min. aver. | 38.9 | 40.3 | 37.4 | 40.5 | 41.4 |
| Speed, R.P.M. | 363 | 363 | 360 | 361 | 358 |
| Speed, ft. per min. | 356 | 356 | 353 | 354 | 351 |
| Minimum coeff. of friction | .01265 | .00717 | .00522 | .00458 | .00367 |

The coefficient of friction in the above table represents the lowest value found for each load, that is, as soon as a given load is applied, the coefficient is, of course, high at first, gradually falling off until it becomes practically constant. This latter figure is the one shown in the table and represents the value that would obtain in ordinary practice where engines operate continuously for more than an hour. The temperature readings given in the table are the highest temperature reached for each load, that is, as each new load is applied, the bearing gradually heats up until the temperature becomes practically constant.

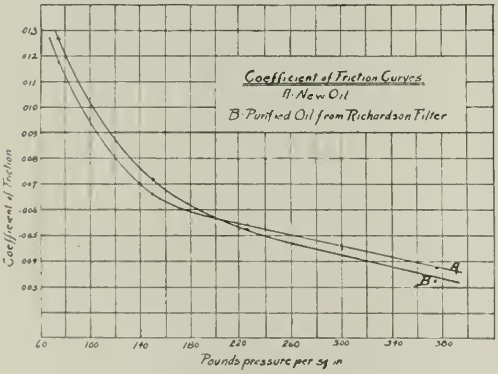

FIG. 1—COEFFICIENT OF FRICTION CURVES

The difference in temperature between the bearing and the room have been plotted in the curves shown in Fig. 2. Curves showing the coefficient of friction of the new and filtered oil are shown in Fig. 1.

As mentioned above, 3 bbl. of new oil are added to this system per month. However, the system as a whole has been in operation for over a year and a half and the question naturally arises, what physical changes, if any, has the oil undergone during this extended period?

The results of tests made to determine this are given in the following tables:

PHYSICAL PROPERTIES
Sample "A"—New Oil

Color: medium red, translucent
Flash point: 410° F. (open cup)
Burning point: 460° F. (open cup)
Specific gravity at 60° F. water as 1 = .895
Viscosity (with Olsen viscosimeter)
Water as 1 at 60° F. Time 27.9 sec. for 100 cc.

| Temperature F. | Time 100cc. secs. | Relative Viscosity |
|---|---|---|
| 70 | 97.0 | 3.48 |
| 70 | 96.6 | 3.46 |
| 71 | 96.2 | 3.45 |
| 97 | 59.8 | 2.14 |
| 94 | 61.8 | 2.21 |
| 130 | 45.6 | 1.63 |
| 132 | 43.8 | 1.57 |
| 214 | 34.0 | 1.22 |
| 215 | 34.2 | 1.225 |

Sample "B"—Purified Oil from Richardson Filter

Color: very dark red, opaque
Flash point: 410° F. (open cup)
Burning point: 440° F. (open cup)
Specific gravity at 60° F. water as 1 = .903
Viscosity (with Olsen viscosimeter)
Water as 1 at 60° F. time 27.9 secs. for 100 cc.

| Temperature F. | Time for 100 cc. secs. | Relative Viscosity |
|---|---|---|
| 68.0 | 138.0 | 4.94 |
| 69.0 | 134.0 | 4.80 |
| 70.0 | 130.2 | 4.66 |
| 103.0 | 60.4 | 2.16 |
| 114.0 | 50.6 | 1.81 |
| 130.0 | 45.2 | 1.62 |
| 152.0 | 39.0 | 1.40 |
| 147.5 | 40.2 | 1.44 |
| 218.0 | 33.2 | 1.19 |

The viscosity readings have been plotted in the form of a curve, shown in Fig. 3.

From the table it is evident that the oil has gained in specific gravity through constant use. This is what one would naturally expect inasmuch as the oil, in passing through the bearings has had some of its more volatile constituents driven off, also a small quantity of cylinder oil used for lubricating the piston rods and stuffing boxes naturally finds its way into the oiling system. The viscosity curves also confirm this hypothesis as the tests show that the used oil has a higher viscosity than the new, clearly demonstrating that as oil is used over and over again in an oiling system it actually gains in body, provided, of course, the filter thoroughly removes entrained water, and this is the vital point of the whole system.

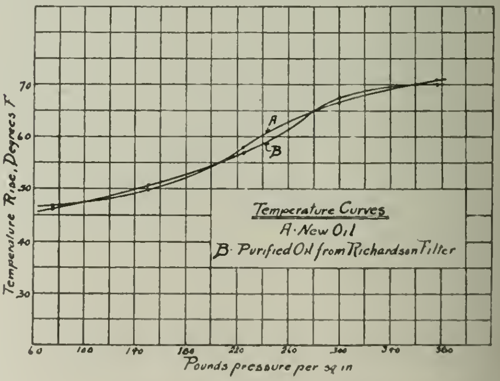

FIG. 2—TEMPERATURE CURVES

The results of the friction tests as shown in Fig. 1 are also consistent with these physical changes. It will be noted that the new oil has a slightly lower coefficient of friction on low bearing pressures, while the purified oil shows a lower coefficient on higher bearing pressures. This is due to the fact just noted. In other words, the old oil, having more body, is better able to maintain a lubricating film when subjected to higher pressures. Of course, the difference between these two curves is so slight that without any fear of contradiction one can say that for all practical purposes, properly filtered oil is as good a lubricant as new oil under all operating conditions.

The curves shown in Fig. 2 are probably the ones that will be most interesting to the operating engineer, as it is usually by the temperature of the bearings that he determines the quality of lubrication. As will be noted, these curves are practically superimposed and in no case is the variation more than a few degrees so that here again it is proven that filtered oil is as good as new oil.

Of course, it is needless to remark that in order to secure such remarkable results a highly efficient filter is necessary and the proposition of thus purifying oil on a commercial basis is naturally of considerable engineering interest. This plant is equipped with two new type Richardson power plant oil filters operating in parallel, each handling an average load of 75 gal. of oil per hour. In the design of these filters special attention has been given to providing a scientific method of precipitation.

Referring to Fig. 3, it will be seen that if the oil is heated to a temperature of about 150 deg. its viscosity is only slightly higher than that of water even after the oil has been in service a long time. Now, if oil at this temperature could be spread out in a very thin film, entrained water and other impurities which are heavier than oil would settle out very rapidly. Of course, it is impossible to spread the oil out very thin in a commercial filter handling large quantities of oil, as the size of the filter would be prohibitive. However, this principle has been utilized in the new Richardson filter. The dirty oil is first heated as it passes into the filter, after which it is carried to the bottom of a precipitation compartment where, by a novel arrangement, the oil is spread out to an area of about 14 sq. ft., but this compartment only occupies 2½ sq. ft. of floor space. The velocity of the oil in passing through this precipitation process is reduced to 0.2067 ft. per second. This extremely low velocity allows plenty of time for the precipitation process to be carried out in a highly efficient manner. The importance of thoroughly separating entrained water from the oil is demonstrated by the fact that at the Hotel McAlpin about 4 gal. of water per day is automatically separated and ejected from the precipitation chambers of the filters.

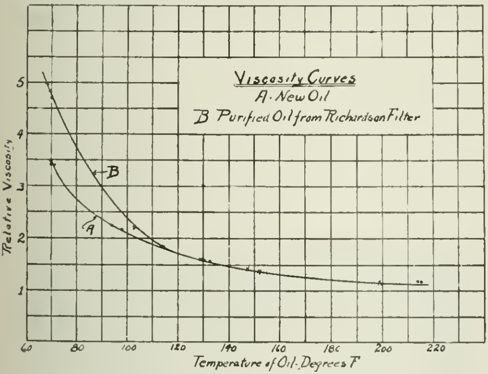

FIG. 3—VISCOSITY CURVES

The oil after being separated from entrained water and heavy particles of foreign matter in the precipitation chamber then passes directly to the filtering chambers, each of which contains twelve filtering units having a total filtering area of 3½ sq. ft. On this basis the filters are handling in a most efficient manner 2.4 gal. of oil per square foot of filtering surface per hour.

As the tests prove that the oil is purified in a remarkable manner, it is thus seen that with a properly designed system of precipitation a large amount of cloth filtering surface is entirely uncalled for. The disposition of the filtering medium is of far more importance than its quantity. It would be just as logical to buy engines by the pound as to purchase an oil filter by amount of filtering surface it is supposed to have and disregard its efficiency. The arrangement of the filtering medium in the Richardson filter is such that it is free from wrinkles and folds. Every square inch of surface is effective and an equal thickness of the filtering medium is interposed in the oil circuit at every point.

Tests have proved that when filtering cloth is adjusted in any manner that constrains it to arrange itself in folds or plaits, the portions of the filtering surface where the folds come interpose a greater thickness and the oil does not pass through these parts but is short-circuited through the single thickness portions, thus rendering large portions of the surface inactive. So efficient has its system of precipitation and filtering proven that the Richardson-Phenix Company has now successfully applied this principle to its entire line of filters, ranging from small hand filters having a capacity of a few quarts per hour to large filters capable of handling over 7500 gal. an hour.

The fact that a power plant like that in the Hotel McAlpin pays for less than two-tenths of 1 per cent of the amount of oil used and that oil can be purified in a commercial filter and returned to an oiling system in a state of purity equal to new oil, is certainly of vast importance in the economical operation of power plants, and the old-fashioned idea of purchasing a barrel of oil and letting it drip to waste is certainly as out of date and uneconomical as Watts' original scheme of condensing the steam directly in the engine cylinder. The saving in the cost of the oil in the above plant by the use of the oiling system amounts to over $2,000 per month, but who can compute the amount of coal saved by the reduction of friction or how much wear and tear on the machinery is reduced. It is safe to say that the money value of these savings is at least as great as the reduction in the oil bill.

The above data was furnished by the engineering department of the Richardson-Phenix Company, lubrication engineers and manufacturers, Milwaukee, Wis.

---

**Transvaal Gold Production.**—The number of companies reporting to the Transvaal Chamber of Mines in December, 1913, was 60. The quantity of ore milled during that period was 2,014,358 tons. There were 9722 stamps in operation, with an average duty of 8.63 tons per 24 hours. Tube mills in commission numbered 287. The yield for the month was 672,815 fine ounces gold. This report shows a marked decrease in tonnage treated and gold recovered as compared with the same month in 1912.

**The International Engineering Congress** is making rapid progress in working out the final program of papers to be presented at the sessions in San Francisco in 1915. The first volume of publications will consist of a series of articles descriptive of the technical features of the design and construction of the Panama canal. Each of the topics will be treated by some one of the canal force who has been responsible for the design and construction described. The program for the other sections of the congress is practically complete, and notices will be published in the near future. Membership in the Congress on March 1 was over 1200.

# A New Continuous and Dustless Dryer for Sludge Material

Drying is often a most trying proposition for chemical and metallurgical engineers, especially if the material to be dried is in a sludgy form and of such a chemical nature that the production of dust would seriously affect the welfare of the workmen.

What appears to be a very interesting and promising advance in the right direction is the recent development of the Macklind annular dryer by the Sherwin-Williams Company, of Cleveland, O., and its first installation at the Ozark Smelting and Mining Company's plant at Coffeyville, Kan.

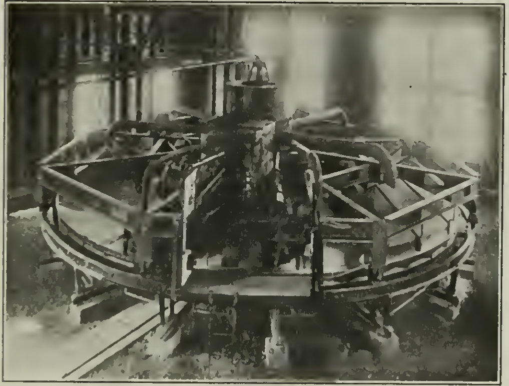

FIG. 1—MACKLIND ANNULAR DRYER AT OZARK SMELTING & MINING CO.

This machine was invented by Mr. W. R. Macklind, Managing Engineer of the Sherwin-Williams Co., and the specific purpose of the design was to produce a dryer that was continuous in operation, dustless and of high efficiency.

The principle of the Macklind dryer is to form a thin film, dry it and remove it in the shortest possible period in order that the material dried cannot be affected by the temperature. For this purpose the dryer is built in annular form and the period during which each film is being fed to the dryer, dried and removed is one revolution of the dryer.

The manner of operating at Coffeyville is as follows: The sludge material to be dried is pumped to the machine, varying from 60 per cent water and 40 per cent solids to 50 per cent water and 50 per cent solids. This sludge is delivered to the feeding cylinder over the feeding device, which device in turn deposits it on the annular surface of the machine. The spider of the machine revolves. The annular drying surface is stationary. The revolving medium makes a revolution every three to one and one-half minutes.

The machine being started, the feeding device thereupon commences to feed the sludge material in a thin film on the drying surface. In turn when the machine has made one revolution from the initial starting point, the removing device commences to operate, removing the dried material and carrying it to the center of the machine for final delivery to the packers.

From this time on the operation is continuous, feeding and removing, and the operator's only duty is to watch the machine and see that it is properly oiled and the proper speed of rotation is kept. This, however, becomes constant after the machine is set.

All vapor arising from the dried material is removed by means of the vapor hoods and connection pipes through the central vapor drum into the atmosphere. The circulation of this vapor-removing medium is carried on through induced draft.

All dust arising from the removing device is collected and deposited in a small bag collecting device in the center of the machine.

The Macklind dryer has been operating for some sixty days at Coffeyville on lead pigment and in addition extensive tests have been made in drying pulp white lead. These tests were carried on in the presence of experts from the National, Eagle White Lead and Hammar Brothers White Lead Works, and are stated to have proven conclusively the efficiency of the machine in drying white lead pulp from the standpoint of efficiency, continuity, rapidity and dustlessness. This latter feature is one of the most important phases of this new machine. The success of the machine in drying sludge white lead dustlessly—which is recognized to be one of the most difficult propositions—appears to open to the Macklind dryer a wide field of usefulness. For this reason the following details of its construction should be of general interest.

The dryer is circular and weighs 80,000 lbs. erected. It is 30 ft. in diameter and requires 14 ft. head room. The surface of the drying table is 40 ins. above the floor. The drying table, which is 6 ft. wide, consists of 40 semi-steel sectors and has a drying surface of 414 sq. ft. The sectors of the drying table are tested to 150 lbs. hydrostatic pressure.

The drying table operates with a pressure of steam from 50 to 90 lbs. The temperature of the drying table at 90 lbs. pressure is 330 deg. F., which is the maximum temperature at which the machine operates. The dryer is operated by three direct-current electric motors of 5 hp, 3 hp and ¾ hp respectively.

The material to be dried is forced by a rotary pump to brass reservoirs over feeding device. This reservoir serves the brass vibratory feeder which places the sludge on the drying table. The pressure of the material being fed is held constant by means of static head maintained by a rotrex pump. The dried material is removed by means of an enclosed removing device.

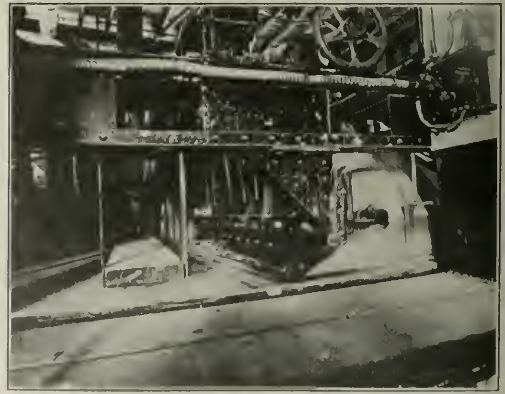

FIG. 2—FEEDING MECHANISM OF DRYER

As described before, the material is dried in one complete revolution. This takes from one to three minutes. White lead and leaded zinc pigments dry thoroughly with no perceptible moisture in one to one and one-half minutes.

The operator can control the rotating speed of the machines at will, so that one revolution may take from one minute to three minutes, or any intervening period.

While the machine will handle sludge materials containing 40 per cent water and 60 per cent solids or 50 per cent and 50 per cent respectively, it will not operate successfully if the sludge does not carry at least 40 per cent of water.

The dried material can be packed direct from machine without pulverizing, if desired, as it is in a granular state.

All vapors arising from the drying process are immediately removed and discharged into the air. The condensation from the drying table handled by trap can be used as pure water for manufacturing or returned to the boilers if desired.

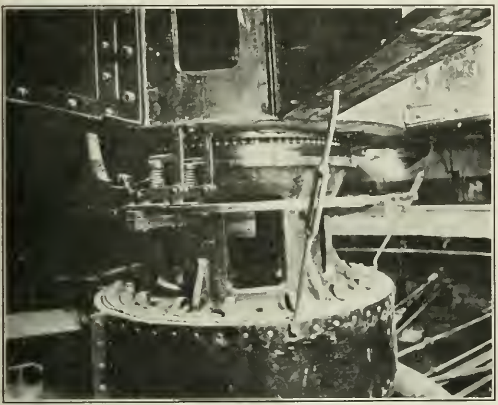

FIG. 3—CENTRAL COLUMN OF DRYER

The machine is operated by one man who has full control of all its movements which are handled from the operating platform which revolves with the machine. All movements are operated by electric motors.

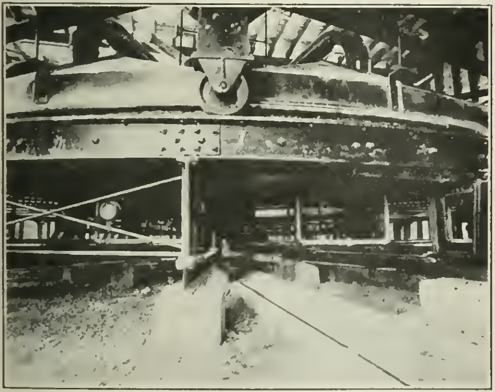

FIG. 5—DETAILS OF DRYER CONSTRUCTION

A dust collector takes care of the dust made in the removing device.

The use of steam in the machine insures an even temperature throughout the annular dryer table. The use of steam makes it possible to regulate the temperature according to the character of material being treated.

The efficiency of this dryer is stated to average about 75 per cent, though it naturally varies, depending on conditions. With dry steam and 50 to 45 per cent sludge a 75 per cent efficiency can be maintained. From the results obtained at Coffeyville it appears that the cost of drying sludge material as compared with dry-pan practice is cut in two.

In calculating the efficiency of the dryer, the formula $E = 100\ a\ b$ is used, where E is the efficiency of the machine, $a$ the heat utilized in evaporating water in the sludge to be dried and $b$ the total heat supplied to the annular table.

While the efficiency was stated before to average 75 per cent, the actual figures obtained with the machine in drying sludge consisting of 55 per cent water and 45 per cent solids were as follows: 2444 lbs. of water were to be evaporated for every 2000 lbs. of dried material. The number of B.t.u. required to evaporate the 2444 lbs. of water was 2,800,824, while the B.t.u. delivered to the annular dryer in the steam was 3,552,000. Therefore, according to the above formula, an efficiency of 78.8 per cent was obtained.

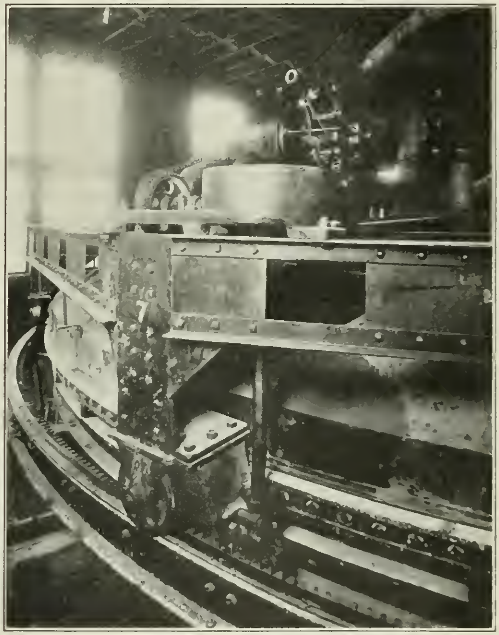

FIG. 4—DETAILS OF DRYER CONSTRUCTION

Fig. 1 shows the Macklind annular dryer as installed in Coffeyville, Kans. While its minimum capacity is 2000 lbs. of dry material per hour (the material going on machine from 55 per cent water and 45 per cent solids), the machine has a record of 3361 lbs. dried material per hour. This rate was maintained for a run of nine hours continuously.

Fig. 2 shows the bronze feeding mechanism of the dryer. This mechanism makes 300 vibrations per minute and sludge material is thereby fed in a perfect film onto the drying surface of the machine, shown directly underneath the feeding device.

Fig. 3 shows the central column of the dryer with the following details: Ball bearings of revolving frame spider, direct-current trolleys for supplying current for operating machine, revolving dust-tight drum connecting with jumper conveyor, which transmits dried material from table to center of machine for discharge.

In Fig. 4 are shown the main motor drive for rotating machine frame, radial rack of machine, details of castor at pinion drive, vapor hoods as suspended above drying table, ends of cast iron sectors showing core drawing plugs, vapor collecting drum in center of machine with main vapor discharge stack and induction air jet.

The details shown in Fig. 5 are steam connections, draining connections to sectors, super-structure frame, foundations, gauges for indicating pressure on sectors, vapor collecting hoods and supporting castor for revolving spider.

As the problem of drying materials in a sludge form comes up so often in chemical and metallurgical practice it will be interesting to watch the further career of the Macklind dryer after it has shown its usefulness for white lead. It is now being put on the market by the Sherwin-Williams Company, 601 Canal Road, Cleveland, Ohio.

## Duriron Castings for Chemical and Metallurgical Purposes

Among recent iron alloys, invented for special purposes, "duriron" is of particular interest to chemical and metallurgical engineers on account of its remarkable resistivity to chemical action.

Duriron is an iron alloy containing from 12 to 15 per cent silicon, while its other ingredients are being kept secret. It is suitable for most chemical apparatus or machines that can be cast and finished by grinding. Duriron is too hard to be machined.

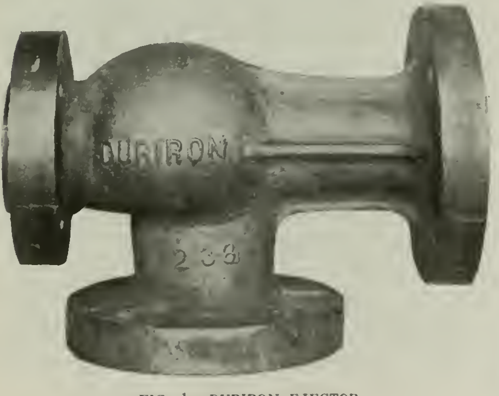

FIG. 1—DURIRON EJECTOR

The specific gravity of duriron is 7; that is, it is 4 to 7 per cent lighter than cast iron. The weight per cubic inch is 0.252 lb.

The tensile strength of duriron is 12,000 lb.; the compression strength 70,000 lb. The melting point is 2550 deg. Fahr. Its heat conductivity is higher than that of cast iron. It takes and retains a polish like nickel. In the design of duriron apparatus its shrinkage and high coefficient of expansion must always be considered. The shrinkage is 3/16 inch to the foot, the coefficient of expansion 0.00001565 per degree Fahr.

The most remarkable property of duriron is, as stated, its resistivity to corrosion. With few exceptions, duriron is not attacked by acids or alkalies of any strength. Of course, the resistivity of duriron to chemical attack depends somewhat on the temperature, decreasing slightly with higher temperatures.

The following results of immersion tests show the action of various acids on duriron.

Immersed in cold 25 per cent sulphuric acid, duriron showed no loss in one year, while cast iron was completely dissolved in sixteen days and wrought iron in thirty days.

Immersed in cold 25 per cent nitric acid, duriron showed a loss of 0.015 per cent in one year, while cast iron was completely dissolved in sixty-three hours and wrought iron in fifty-eight hours.

From results in actual practice it may further be stated that duriron is unaffected by acetic, tannic, hydrofluosilicic acid, copper sulphate, etc. It is resistant to phosphoric acid up to a certain strength, and is sometimes attacked by sulphurous acid. Duriron connecting-pipes of nitric and sulphuric acid stills have shown no apparent corrosion after one year of service.

The experience of a large aniline-color manufacturing plant is particularly suggestive. They have determined that in dyeing wool and cotton exactly the same shade and color may be obtained in duriron vessels as in porcelain. The slightest trace of dissolved iron would have a marked effect on the resultant color.

As to the resistivity of duriron to mechanical erosion as distinguished from chemical corrosion the report on the behavior of a duriron scraper in a salt cake furnace is interesting. In twenty-eight days of continuous operation at 900 deg. Fahr. the duriron scraper wore down ½ in., while cast-iron scrapers under the same conditions of operation wore down 3 inches. On account of this remarkable resistivity to erosion duriron is now being considered in connection with pneumatic ash-conveyor systems.

The adjoining illustrations show some interesting castings for chemical and general industrial work built by the Duriron Castings Company, 90 West Street, New York City, in their foundry in Dayton, Ohio.

Fig. 1 shows a steam syphon of duriron. One has been in use since last September with strong sulphate of alumina and so far not the slightest trace of corrosion or erosion has been found.

Fig. 2 shows a duriron centrifugal pump. In this case both the resistivity of the duriron to chemical attack by acids and its resistivity to erosion by grit and hard material are proving to be of greatest advantage. These pumps are of a very refined design and embody various features of particular value in pumps for handling acids.

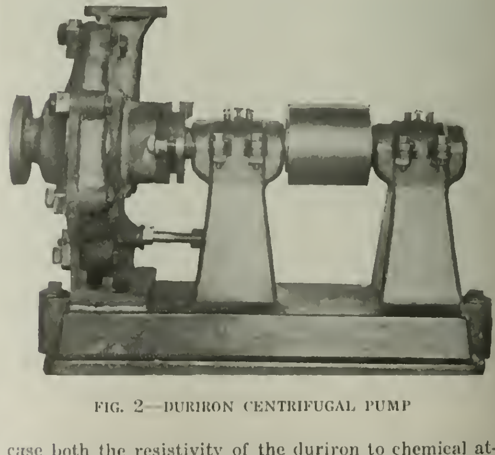

FIG. 2—DURIRON CENTRIFUGAL PUMP

Fig. 3 shows a partial installation of standard duriron pipe and a regular duriron cock, slightly modified to meet conditions. This standard pipe can be cut to length on order, and the use of compression couplings not only insures a stronger line, but each coupling constitutes an expansion joint. The Duriron Castings Co. also manufacture all kinds of special pipe. This pipe is used not only in chemical and metallurgical works, but is now also being widely employed in municipal water systems as they are not affected in the least by the sulphate of alumina solution employed in rapid filtration systems or by hypochlorite solutions now so generally employed as an after-treatment in water purification.

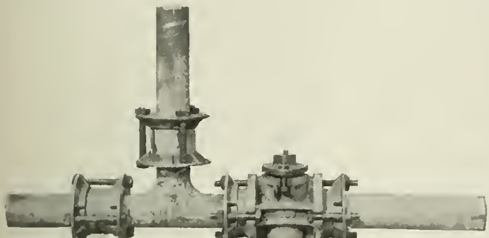

FIG. 3—DURIRON STANDARD PIPE INSTALLATION

Duriron cocks have recently undergone a careful redesign and reconstruction in which among other things special attention has been paid to correct taper which in general is hardly given the attention it deserves. As an illustration of their durability it may be stated that after months of continuous service, handling mixed acid (nitric as low as 18 per cent.) at 80 lbs. pressure, no corrosion or erosion could be detected. One of the great practical advantages of duriron cocks is that they do not stick even after long periods of idleness. Some users never grease them, some grease every four or five months, and others every four or five weeks. Their cost of maintenance is, therefore, very slight.

## A Small-Size Electric Arc Furnace for Melting and Refining

In 1912, Mr. Ivar Rennerfelt, a Swedish engineer, constructed at Hallstahammar, Sweden, an electric furnace, embodying some interesting novel features. The trial was so successful that, within a year, a steel foundry containing four Rennerfelt furnaces was erected at Hallstahammar.

Since then eleven other Rennerfelt furnaces have been erected or are in course of construction in various other plants in Sweden, Norway and Russia.

The principal field of the furnace is that of an economical small furnace for crucible works, steel foundries, copper and alloy foundries, etc. Its principle is applicable to small units of 100 kg as well as larger sizes, and the capacity can be multiplied almost at will by putting together a number of units as will be described later.

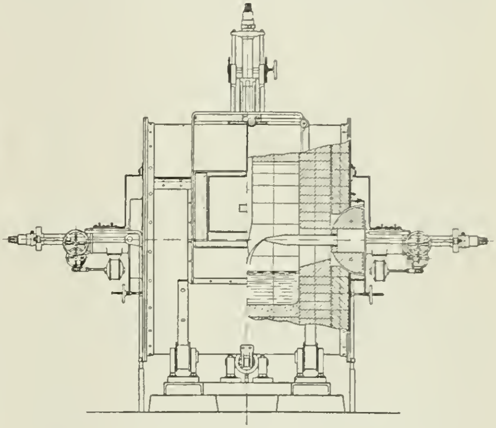

FIG. 3.—MODIFIED DESIGN

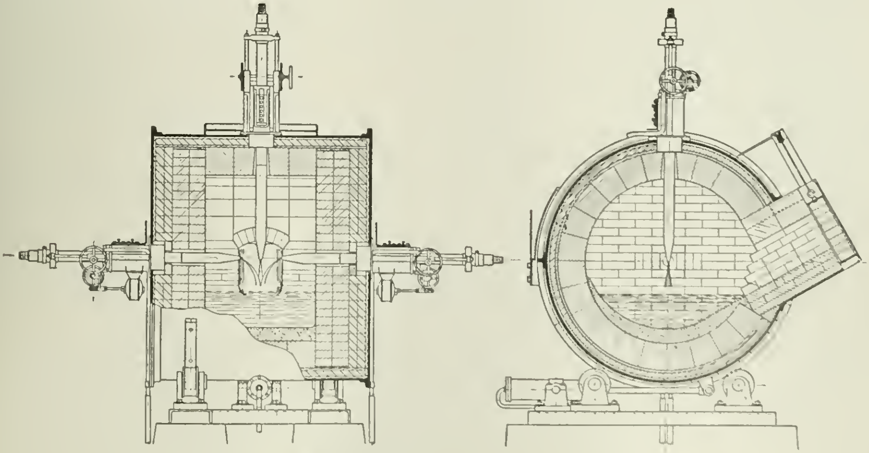
The Rennerfelt furnace is essentially a two-phase furnace. In case the plant is supplied with three-phase currents the well-known Scott transformation is employed to change the three-phase to two-phase currents.

There are three electrodes; one central electrode descending vertically through the crown of the roof, flanked on both sides by horizontal electrodes entering through the sides of the furnace. Fig. 1 shows the arrangement of electrodes with the side-electrodes sliding in fixed holders, but adjustable axially by hand or motor power. Fig. 2 represents a section of the same fur-



FIGS. 1 AND 2.—TWO VERTICAL SECTIONS OF RENNERFELT FURNACE

nace showing the charging and casting door placed in the circular wall.

Fig. 3 shows a sectional view of a furnace with the horizontal electrodes adjustable in the vertical plane. Electrodes adjustable vertically are preferably used when the furnace is employed for melting light scrap, requiring much space below the arcs, before it is melted.

The two side electrodes are connected to the two phases of the two-phase system respectively, while the vertical top electrode is connected to the neutral point. Fig. 4 shows clearly the electrical connections.

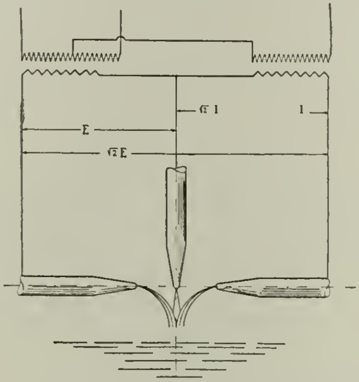


FIG. 4—ELECTRIC CONNECTIONS OF ELECTRODES

The principal novel feature of the Rennerfelt furnace is that as a result of the magnetic fields produced by the currents in the electrodes and in the arcs themselves, the arcs are deflected downwards onto the bath, thus forming the arcs into an inverted arrowhead or *fleud-de-lys*. The heat generated in the arcs is thus concentrated down upon the bath, though the electrodes do not touch or even approach the slag or metal. The arcs are sweeping or brushing all over the central space underneath the points of the electrodes, insuring a uniform heating of the charge and rendering the slag very fluid and chemically active. The height of the arcs from the points of the electrodes to the surface of the bath can be adjusted, but is usually kept at about 6 to 12 in.

In the riveted and strongly braced steel shell of the furnace is placed an insulating lining of asbestos board. Silica or first-quality firebricks in rings are built up against the asbestos board and form the bedding for the actual inner lining, acid or basic. This is made of special bricks requiring no cutting and set in rings of different diameters so as to form an egg-shaped interior melting chamber. The bull's eye around the charging door is carefully fitted into the lining. Special bricks form circular openings through which the electrodes enter into the furnace.

The life of the lining has not yet been finally established during the few months of actual operation, but a furnace with basic roof and hearth has run 102 heats without requiring any repairs outside of the ordinary fettling. A furnace with acid roof and lining operated continually day and night during two months and a half on acid tool steel, running not less than 174 heats. The temperature in the basic was kept considerably higher than in the acid furnace. The bottom of the hearth is practically undestroyable and may be used over again continuously when repairing the side walls and the roof.

The radiating heat from the free-burning arcs is reflected on to the bath from the entire mirror-like incandescent inner surface of the vault. Yet the arcs are at such a distance from this roof that the danger of melting the same is minimized. The shadow of the vertical electrode has a marked protecting influence on the vulnerable portion of the vault—the area around the entrance opening for the said electrode.

There is no sudden break between the roof, sidewalls and bottom, all being built together in one continuous curve. Owing to the circular form of the roof, the arch is very strong, and the disadvantage of expansion and contraction of the lining is greatly reduced.

As to the consumption of the electrodes the following information is given:

In a 600-kg. (1320-lb.) furnace running continually on charges of cold scrap and pig the average consumption of electrodes has been found to be about 2.8 kg. (6.2 lb.) per ton of steel. This figure represents the gross consumption, as there are no stumps left unconsumed.

Even when melting pig iron and afterward decarbonizing it by means of ore, the consumption of electrodes has not exceeded 3 kg. (6.6 lb.) per ton, in spite of the highly oxidized slag carried on the charge.

The wear of the side electrodes in a small furnace with acid lining using side electrodes of 2-inch diameter amounts to about 1 inch of electrode per hour.

Three such electrodes being used, wear of the electrodes in 24 hours will equal about 6 kg. (13.2 lb.). If the furnace is kept running at full power, 5 heats of 600 kg. (1320 lb.) or 3 tons of steel are produced in 24 hours, making the consumption of electrodes 2 kg. (4.4 lb.) per ton, if reasonable care is exercised.

The power factor is stated to be above 0.9. In one instance a value of 0.97 has been ascertained at a furnace operated with a current of 50 periods.

As to specific power consumption the following data are given:

According to records taken by registering kw-hour-meters a small furnace of 600 kg. (1320 lb.) at the Ljusne ironworks melted and refined a full charge of cold scrap with not more than 700 kw-hr. per ton. The normal rating of a furnace of this capacity is 125 kw, but according to records 80 to 90 kw are sufficient to complete a 600 kg. heat in 5 hours' time, indicating a very satisfactory thermal efficiency even when running with only 75 per cent. of full load. White pig iron has been melted in the same furnace under similar conditions with 405 kw-hr. per ton. This figure is an average of four consecutive records.

In one instance gray pig iron was melted and overheated with 425 kw-hr. per ton, including the melting of 22 kg. basic slag per ton of iron. Under very favorable conditions it has, however, been possible to melt gray pig iron with about 300 kw-hr. per ton in a 600-kg. furnace.

Repeated and successful trial runs have proven that the Rennerfelt furnace is also well suited for producing high-grade tool steel from pig and ore. As indicated by recording meters a ton of pig iron charged cold can be converted into steel in a fairly large furnace with a consumption of about 850 kw-hr. If the iron is charged liquid, 350 kw-hr. may be saved; 500 kw-hr. would, therefore, suffice to decompose the ore required and to deoxidize the steel resulting from 1 ton of liquid pig metal.

The furnace is being used for steel foundry work producing excellent castings, thin-walled and of intricate forms. The steel is tapped very hot and often requires to be held in the ladle for sometime until sufficiently cooled off to make good castings. Cracks due to shrinkage and blowholes seldom occur in steel foundries using this type of furnace. Nickel-steel castings, manganese steel and acid tool steel have all been successfully made in the furnace. Motor-cylinders and other high-class pieces in pig iron have also been cast with perfectly satisfactory results.

The Rennerfelt furnace has also been employed for copper and brass melting. A small furnace of about 60 kw was charged with 95 kg. copper after having been brought to full temperature. The charge was completely melted after 30 minutes with an expenditure of 30 kw-hr. or about 300 kw-hr. per ton. Another charge of 44.5 kg. copper and 30 kg. zinc was entirely melted after 20 minutes, the energy consumed being 20 kw-hr. or 268 kw-hr. per ton of brass. The metal was poured into ingot molds and afterward drawn into tubes of excellent quality. At another occasion, the furnace was used for melting about 350 kg. of copper scrap with satisfactory results, the charge melting in a few minutes. The copper was perfectly dead and was cast into small blocks.

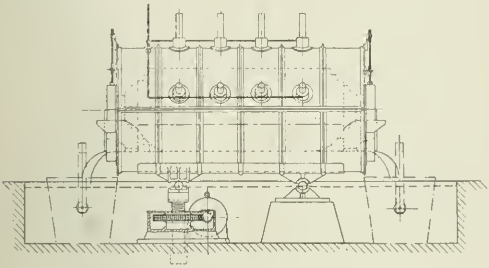

FIG. 5—MULTIPLE-UNIT FURNACE

The energy consumed per ton will, of course, be materially reduced, when dealing with larger charges in furnaces especially designed for special metals. The figures already obtained indicate, however, that the furnace will successfully compete with the crucible in brass foundries, especially as there is practically no loss from oxidation and as the metal is materially improved.

In order to make this furnace adaptable to large sizes, the "multiple-unit arc furnace" design is employed as shown in Fig. 5, which illustrates a furnace made up of four unit sizes side by side. The furnace is built as an elongated crucible of preferably cylindrically cross-section, made up of a number of similar sections bolted to one another and each fitted with one set of electrodes.

The patent rights of the Rennerfelt furnace are owned by the Aktiebolaget Elektriska, Ugnar, Fredsgatan 2, Stockholm, Sweden.

## Personal

Mr. **G. D. Van Arsdale**, chemist for the Phelps-Dodge interests at Douglas, Ariz. stopped in Denver last month to visit the plant of the National Radium Institute, of which Dr. James Douglas is one of the organizers. Mr. Van Arsdale will return to Arizona in about a month, after a trip through the East.

Mr. **Charles F. Burgess**, who for a number of years has been in charge of the Chemical Engineering and Applied Electrochemical Departments of the University of Wisconsin, has resigned his professorship to devote himself to the management of the Northern Chemical Engineering Laboratories with offices at Madison, Wisconsin. These laboratories are carrying on experimental and development work in chemical, electrochemical, and metallurgical engineering. Included in its technical staff are Carl Hambuechen, E. E.; Otto E. Ruhoff, B. S.; Walter B. Schulte, Ch. E.; L. T. Richardson, Ch. E.; O. W. Storey, Ch. E., and Arden R. Johnson, Ph. D.

Mr. **Charles Butters** has returned to this country from a visit to Salvador where he inspected the Butters properties.

Mr. **Franklin Guiterman**, of the New York office of the American Smelting & Refining Co., has been making a trip of inspection among the Colorado smelting plants owned by the company.

Mr. **J. M. Hyde** has returned to this country after a trip through Europe investigating new metallurgical processes. He will be American representative for the Murex Magnetic Co., Ltd., with headquarters at San Francisco.

Mr. **E. M. Johnson** has resigned his position as manager for the National Zinc Co.

Mr. **W. D. Leonard**, superintendent of the Garfield smelter of the American Smelter Securities Co., made a brief visit in Denver last month.

Mr. **L. M. Marshall** has severed his connection with the Cambria Steel Company to become chief engineer and assistant general manager of Messrs. A. J. Haws & Sons, Ltd., refractory manufacturers of Johnstown, Pa.

Dr. **Charles L. Parsons**, chief of the division of mineral technology, U. S. Bureau of Mines, has been in Denver to inspect the newly completed plant of the National Radium Institute, which is to be operated under an agreement between the Bureau and the Institute.

Mr. **August Raht**, who was closely identified with the early development of smelting in Colorado, was in Denver last month on a visit from his home in Santa Cruz, Cal.

Mr. **W. H. Staver**, formerly superintendent for the Liberty Bell company in Colorado, is engaged in cyanide experiments at Sonora, Tuolumne county, Cal.

Mr. **F. D. Weeks**, of the American Metal Co., spent a part of March in Colorado, visiting the Denver offices and Salida smelting plant.

## Digest of Electrochemical U. S. Patents.

PRIOR TO 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

### ELECTROPLATING

3015, March 21, 1843, Daniel Davis, Jr., of Boston, Mass.

Relates to electroplating, particularly to electrogilding, and produces a "dead-gilding" effect by first electroplating with copper, then a layer of gold, or of the metal required. The layer of copper produces a deadening of the final layer in a thorough and beautiful manner. With iron objects, cyanide of potassium is added to the copper sulphate solution sufficient to produce a solution of the copper in the cyanide of potassium. The iron is then coated with copper from this solution, after which a thicker coating may be applied from the sulphate solution. The gold is then deposited.

17,095, April 21, 1857, Alonzo G. Hull, of New York, N. Y.

Relates to electrolytic apparatus for medical use, and consists of two cells communicating through a submerged, porous diaphragm through which also is a valved opening. When the valve is opened, a graduated amount of circulation of the liquid takes place; when closed, the porous diaphragm allows electric action to take place.

26,978, January 31, 1860, Matthew Edwards, of Cambridge, Mass.

Relates to oxidizing metals for ornamental purposes, and consists in connecting the metal to be oxidized as an anode in a suitable electrolyte. With copper or brass, and an electrolyte of sodium chloride, a black coating is deposited, while with an electrolyte of potassium chlorate the metal will be colored red. If the surface contains silver or other white metal, weaker electrolytes are used.

27,046, February 7, 1860, William B. Gillett, of Auburn, N. Y.

Relates to sharpening files by electrolysis. The file is connected as an anode in an electrolyte of dilute sulphuric acid, or of a suitable salt, the cathode constituting a metallic plate, or the metallic lining of the tank. The file may also constitute the electropositive element of a voltaic cell.

82,525, September 29, 1868, Maurice Herrmann Jacobi and Eugene Klein, of St. Petersburg, Russia, assignors to Green, Clay & Company.

Relates to the electrodeposition of iron on molds for engraving, stereotypes, etc. The electrolyte consists of sulphate of iron combined with the sulphates of either ammonia, potash, or soda; or the chlorides of these metals may be used with the sulphate of iron. The bath should be kept as neutral as possible, but a small quantity of weak organic acid may be present to prevent precipitation of basic compounds of iron. A small quantity of gelatine improves the texture of the iron deposit. In order to increase the rate of solution of the iron anode, thereby maintaining the strength of the electrolyte, the anode may be short-circuited with a piece of gas carbon, or other electronegative element, the carbon being placed in the same electrolyte, or in a separate porous cell.

89,523, April 27, 1869, Hiram Tucker, of Newton, Mass.

Relates to ornamenting metal articles by electroplating, and consists in first enameling or varnishing the article, then grinding or otherwise removing portions of the coating, and electrodepositing the desired metal on the exposed parts.

90,894, June 1, 1869, Hiram Tucker, of Newton, Mass.

Relates to ornamenting metal articles by electroplating; it resembles the process described in patent No. 89,523, except that a final "show coating" of gold, etc., is deposited on the exposed metal.

97,390, November 30, 1869, Kingston Goddard, of Richmond, N. Y.

Relates to electroplating articles such as pitchers, etc., made of wood or other non-conducting material. The wood or other material is coated with plumbago, or other suitable conducting material, and electroplated with one or more coats of suitable metal.

97,657, December 7, 1869, Reuben Lighthall, of Brooklyn, N. Y.

(Reissued as No. 4048, June 28, 1870.)

Relates to preventing or retarding the oxidation of iron when in contact with water, especially salt water, and consists in the application to the iron of such electropositive metals as zinc, or alloys of zinc and tin, etc., or the two metals separately. The electropositive metal may be fastened under a bolt, or otherwise, to surface condensers, pipes, ships, etc.

100,038, February 22, 1870, James Spooner Howard, of Mansfield, assignor to himself; E. Adams, Jr., of Attleboro; T. E. Grover, of Mansfield, and N. Carpenter, of Attleboro, Mass.

Relates to electroplating antimony; the solution is made up of six fluid ounces of sulphate of ammonia, one-fourth fluid ounce of cyanide of potassium, eight fluid ounces of sulphate of antimony, and one gallon of (soft) water. The solution is finally filtered. The proportions given may be varied to a small extent.

100,580, March 8, 1870, Elbridge G. Wright, of Boston, Mass.

Relates to ornamenting metals, etc., by electroplating, and consists in coating the article with a suitable resist, removing portions of the resist where it is desired to deposit, and cutting below the surface of the metal so that the deposit will be below the rest of the surface, thereby protecting it from being worn off when exposed, or while being cleaned, etc.

106,823, August 30, 1870, James Spooner Howard, of Mansfield, assignor to himself; T. E. Grover, of same place; E. Adams, Jr., and N. Carpenter, of Attleboro, Mass.

Relates to producing a permanent dull finish upon gun-barrels, etc., and consists in first nickel-plating the object, then electroplating iron upon the nickel; the iron is then oxidized with a solution consisting of ½ oz. copperas, 2 oz. corrosive sublimate, 2 oz. blue vitriol, 3 oz. spirits of niter, ⅛ oz. nitric acid, 2 qt. water. Several applications of this solution are applied to the iron deposit, an hour or more elapsing between successive applications, depending upon the color of finish desired.

109,508, November 22, 1870, Cornelius Godfrey and Reuben Lighthall, of New York, N. Y.

Relates to preventing iron from rusting, and consists in electrodepositing an electropositive metal, as zinc, or alloy, such as alloys of zinc and tin, on the iron to be protected.

113,090, March 28, 1871, John J. Pratt, of New York, N. Y.

Relates to the manufacture of sign plates, etc., and consists in painting letters and numbers with a suitable resist on a metal surface, electroplating the unpainted portions with a desired metal, and then removing the resist, exposing the letters and numbers in the underlying metal below the electroplated surface.

129,207, July 16, 1872, Leopold Brandeis, of Brooklyn, N. Y.

Relates to bronzing columns, pillars, monuments, etc., of iron, and consists in cleaning them with a sand blast, then applying a coating of copper from a solution of a copper salt, or by electrodeposition, then electrodepositing a coating of zinc or lead. If a bronze-antique is desired, a second deposit of copper is made on the zinc or lead coat.

149,974, April 21, 1874, George W. Beardslee, of Brooklyn, N. Y.

Relates to electrodepositing cobalt, and describes preparing an electrolyte by dissolving metallic cobalt in hydrochloric acid, evaporating the solution to dryness, dissolving from 4 to 6 oz. of the salt in a gallon of distilled water, and adding ammonia until the solution is slightly alkaline. The anode consists of cobalt granules or fragments surrounding a carbon plate, and enclosed in a porous sack or envelope. During electrolysis, care should be exercised that the electrolyte remains alkaline.

172,862, February 1, 1876, Isaac Adams, Jr., of Boston, Mass.

Relates to the electroplating of cobalt. Refers to the prior art as found in literature, and points out the disadvantages of several processes. Describes methods of preparing the double chloride of cobalt and ammonium, and of cobalt and magnesium; also the double sulphate of cobalt and ammonium, and of cobalt and magnesium. These salts are dissolved in water to a strength of 6° to 7° Baumé, and maintained neutral. Metallic cobalt is used for the anode, made by reducing tartrate of cobalt with lampblack in a hessian crucible. When electrodepositing on zinc, first give the zinc a coating of copper.

## Industrial Peace

This country has suddenly become involved in a double war. Besides the war with Mexico we have the civil war in the Southern Colorado coal fields. While this journal is neither a mining paper nor a coal paper, the Colorado civil war is of such broad significance for our whole industrial life as to require comment.

We do not dispute in the least the wisdom of the operators to refuse to arbitrate the right of non-union men to work. But we seriously doubt their wisdom of refusing in the beginning any mediation whatsoever when besides the fundamental union principle, some five other points concerning the eight-hour working day, wages, etc., were at issue. It seems to us that then and there the operators lost a splendid opportunity to secure by diplomacy the moral support of the public.

Men are changing and things can no longer be run as they were run twenty or ten years ago. The president of a large public service corporation who recoined a famous old phrase into "The public be pleased" read the signs of the times correctly. In this new age made by the peaceful work of the engineer, only such policies can and will succeed as make for satisfactory relations between employer and employee for satisfactory relations between investors, utilities, and the public—for industrial peace.

## Copper Hydrometallurgy at Chuquicamata

Interest in copper hydrometallurgy justly centers in the work of the Chile Exploration Company at Chuquicamata, Chile, and the interesting experimental work which has been carried on in this country for over a year under the direction of Mr. E. A. Cappelen Smith. In studying Mr. Smith's description of the Chuquicamata copper deposits and the metallurgical investigations thereon, which we present on another page in this issue, the reader will be struck with the element of scientific, as well as financial, adventure which surrounds the past and future of this project.

Truly, a tremendous task has been assigned to metallurgical engineering. Responsibility for the expenditure of millions is imposed on a comparatively small group of engineers, in whom, also, the investors place their hope of financial success.

It may be argued that all mining and metallurgical schemes are, or should be, similarly conceived and executed, but in this instance we find some unusual factors. Precedent cannot guide; ingenuity must point the way; reliance must be placed on comparatively small tests; foresight must meet unusual conditions in a foreign land that is far distant from centers of manufacture and supply. In short, every detail must be worked out and proved successful here before it can be applied there.

And yet the thought presents itself that there are some elements in a venture of this kind that cannot be ascertained with absolute certainty, but only within limitations. Thus, only 600 tons of Chuquicamata ore have been treated experimentally in this country. The ore developed at the mines amounts probably to oved 200,000,000 tons. How truly representative of the ore-body is the quantity tested? We may assume that it is as representative as engineering skill could make it; and yet it does not compare in quantity with the amount of ore treated experimentally by, say the large copper companies in this country, before they settled definitely on their scheme of treatment and erected large mills. Six hundred tons of ore is not a large test-lot. Inspiration has prepared to treat that much per day in an experimental mill for concentration and flotation—processes that are reasonably well known and successful elsewhere.

This illustrates fairly the exceptional features of the Chilean project; probably it was more expedient to bring a small parcel of ore to a test plant conveniently situated, than to erect an experimental unit at the mines.

Other features of metallurgical adventure in the Chuquicamata project are found in the problems that called for original solution. The removal of chlorine from the copper solution, the selection of suitable anode material, the acid-proofing of concrete vats, and the mechanical methods of handling large quantities of ore, all presented interesting subjects for research. Apparently they have been dealt with successfully, and in a comparatively short time.

Not the least point of interest in the whole matter is the evident change in the attitude toward copper hydrometallurgy as evidenced by the magnitude of the project and the spirit with which it has been undertaken. Mr. Smith has been confronted with a problem which, in point of magnitude and novelty, has never been undertaken before. He has the best wishes of the metallurgical fraternity for the ultimate success of the venture.

## Federal Mining and Metallurgical Legislation

Until the Mexican situation demanded practically its entire attention, Congress exhibited signs of activity in legislating for the mining industry. The Senate was considering a bill to codify and suggest amendments to the general mining laws, and the House was concerned with a measure providing for the establishment and maintenance of metallurgical experiment stations. It was hoped and expected by the sponsors for these bills that they might be passed at the present session of Congress. As the bills stand it is doubtful if their provisions are wholly wise. They are open to serious criticism.

Sentiment among engineers and operators is generally favorable to a revision of the mining law, and the leading mining and metallurgical societies have had excellent committees working on suggestions. The present mining law was based on the knowledge of the science and art of mining many years ago. Since that time our knowledge has increased many fold; mining geology has revealed many new facts; general mining experience has proved the deficiency of the old law.

For the purpose of revision the Senate proposes the appointment of a commission of three members; two of whom shall be lawyers experienced in the practice of mining law, and one a mining engineer of practical experience in mine operation. It seems to us that this proposal is typical of legislation conceived by men not fully in touch with the practical conditions in the industry; and we believe that we voice the sentiments of many engineers when we suggest that this commission is not large enough and that there should be a preponderance of mining engineers and geologists instead of lawyers. The latter will be indispensable in properly framing the changes which the former suggest as a result of their knowledge and experience in mining; but the burden of suggesting changes naturally falls on those conversant with actual conditions. Therefore, one engineer is not enough; there should be at least three. These, with two lawyers, might reasonably expect to report amendments that could be adopted with the least disturbance in the industry.

In regard to the bill for metallurgical experiment stations, the features can be briefly stated as follows: Ten "mining experiment stations" are to be established in the United States and Alaska, under the control of the Secretary of the Interior. Each station is to be in charge of an engineer and a metallurgical chemist who shall receive annual salaries not exceeding $4,000 and $3,000, respectively. Each station is to receive an annual appropriation of $25,000 to buy supplies and equipment, and to pay salaries. The Secretary of the Interior may accept contributions of land, buildings, supplies or money from states desiring to cooperate with the Government in the establishment of these stations. Each of the stations, under the direction of the Bureau of Mines, shall make investigations in the mining and treatment of ores, with a view to increasing efficiency in methods and preventing waste, and shall disseminate practical information on these subjects.

A serious objection to this bill is the division of funds. An annual appropriation of $250,000 for the Bureau of Mines is a matter very different from appropriations of $25,000 each for ten experiment stations. Under the provisions of the bill there will not be enough money available for any one station to enable it to carry on serious investigations of any consequence, and there must inevitably be a duplication of work. In other words, the total appropriation will be spread out so thin as to be of little value; it will be consumed largely in maintenance and salaries. Under these conditions it is doubtful if the Government could produce appropriate results.

Perhaps the framing of the provisions of this bill is dictated, to some extent, by political necessity. In order to secure support for the expenditure of such a large sum of money, the appropriation is scattered over a large area and divided among a number of states. This may be good politics, but we believe it is not in the best interests of the industry. If funds are to be provided for mining and metallurgical investigations, they ought to be concentrated instead of scattered.

## A Change in Engineering Education

Columbia University announces a change in the conditions for admission to its engineering schools. Candidates will be required to present evidence of preparation in general educational subjects equivalent to three years' study in the regular college course. Such a procedure has been done already at Harvard and is similar to German custom. This is what is required of the candidates for law and medicine and is a recognition of engineering as a profession of the same dignity as law and medicine and requiring much the same educational foundation. With the splendid facilities offered by Columbia this raising of the standard will give us an engineering school of as high a rank as any in the world. At Harvard the graduates receive the title of Doctor of Engineering.

The effect of this on the profession cannot be other than good. Of course, there will always appear occasionally a young man bound to acquire an education while engaged in practical work, as Abraham Lincoln made himself master of his profession without any educational advantages. If another John Fritz should be born he would be John Fritz still, even if he never earned an academic degree, just as Faraday was a great physicist and electrician by nature. It is possible that men of this type would not be helped by a technical education; indeed, some psychologists hold that they would be injured by making the initial steps too easy. But they are exceptional, probably we shall see only a few in a century, and educational institutions are intended for the general run of mankind. Again, there will always rise from the ranks men of executive ability, who pick up a scientific knowledge in the hard school of experience, and make invaluable superintendents or managers. Such men are entitled to be called engineers even if they cannot write two letters after their names. Such men, too, are not common, for executive ability is a gift of the highest value if combined with common sense and a kindly disposition.

Now the great body of men need training in theory as well as in the school of experience. Columbia will furnish a technical training of high grade, and it is wise to base this on some general culture, so that an engineer with a degree of Doctor of Engineering will have a working knowledge of at least one foreign language, an ability to write plain and forcible English, and a habit of taking broad views, created by some economic and historical study. On a cultural foundation it is intended to build professional training, and when to this professional training is added ten years of practical work her graduates ought to prove good all-round men and some of them engineers of a high grade. To repeat: there are some men bound to forge to the front in the engineering and in any other profession without much aid from educational training, but the great body of men must be trained early and started right. This, modern education proposes to do, merely insisting that the young men she teaches shall come to her with a knowledge in outside subjects equivalent to what they would acquire by three years of college. Then she will teach them more in a year than they could learn in five in the rough and tumble of practical work.

Many graduates of professional schools never follow up the profession; for instance, an opening in a patent lawyer's office may give one an opportunity and he takes it. Some graduates of the engineering schools will doubtless drift into other employments. A well-trained engineer can easily become a patent lawyer. Conversely a patent lawyer should know more than he usually does about engineering. The big cases turn on engineering questions. The engineer also sometimes makes a good business man. But the great benefit of an education not used for its earning capacity is that it gives an interest in life. To an engineer a mine, a smelter, a machine shop, an electrical plant, are objects of the highest interest, as much so as forest is to the trained forester. The more he knows, the keener his interest, and to take an intelligent interest is really to live, and to produce results.

There is a peculiar fitness in making Columbia the center of a great technical school. Its first president, Samuel Johnson, a great Hebrew scholar, was a friend and admirer of Benjamin Franklin, who had an influence on him and Columbia. He conceived the idea of having what was then called "natural philosophy" taught in the college which he was founding. The correspondence between the two shows the interest felt in electricity at "King's College" even at that early date. Neither of these men could have imagined that this germ should grow into the School of Mines and later into the three great affiliated schools of science which are now to be raised to a higher plane. The methods of teaching science have developed as rapidly as science itself, to which "the Arts" so long revered as the acme of education are now to furnish a preliminary training.

## The Wage Problem in the Steel Industry

The wage problem in the steel industry is peculiarly complicated. The problem has its practical, its economical, its technical, its sociological and even its legal aspect. To speak of the legal aspect of a wage problem may seem strange, when there are no contracts to speak of between manufacturers and men, yet there is undoubtedly a legal aspect to this problem. The United States Steel Corporation, which makes approximately one-half the steel in the country, is defending a suit brought in October, 1911, for its dissolution, so that it is practically fighting for its very life. In its defense it has cited its liberal, enlightened and progressive treatment of its employees as one of its *raisons d'être*. It can be cited as a fact that the management of the steel corporation is strongly opposed to wages being reduced. It would be unfair, and we believe entirely incorrect, to infer that the pendency of the dissolution suit has anything to do with its attitude; but it is perfectly fair to hold that were there no other considerations the management would be justified, as men commonly look at things, to avoid a wage reduction when its conduct is being scrutinized from the standpoint of the common welfare. In another respect the wage problem has a legal aspect, for when it developed recently that a number of independent steel manufacturers had conferred in Pittsburgh relative to the advisability of reducing wages, a resolution was promptly introduced in Congress that the subject be investigated.

Experts in steel market conditions and movements insist with one voice that a reduction in wages would not widen the margin between production cost and selling prices. The steel market is wide open and strongly competitive, presenting a contrast to conditions which prevailed frequently prior to 1911, and the opinion is strongly expressed that a saving through a wage reduction would immediately be given away to the buyers of steel, the only effect upon the volume of business being to delay buying until buyers became assured that the full measure of the saving in wages was written into market prices. Thus from the practical or commercial viewpoint the question of reducing wages may be dismissed without further discussion.

From the economic aspect the problem is a much more difficult one. Two things usually are granted, that the division between labor and capital in manufacturing should be equitable, and that wages should be arranged with reference to the cost of living. When applied to the steel industry, however, these principles have opposite applications. Selling prices of steel are extremely low. They are but slightly above their historic low point of the late nineties and the subsidiary low point reached somewhat more than two years ago. They are very far below their high points of 1899, 1902, 1906-07 and 1909-10. Indeed, in all the past the tonnage sold at prices lower than those now prevailing is an insignificant percentage of the total tonnage which has been produced. The present wage rates, however, which date from the general advance of February, 1912, are the highest ever paid. According to the principle of equitable division between labor and capital, wages should now be reduced. But according to the other principle, involving the cost of living, they should not be reduced, for the last advance was based upon an increase in the cost of living and there has not since been any measurable decrease in that cost. By reason of these divergent showings, the study from the economic aspect gives no clear suggestion.

The sociologic aspect gives much more promise, but is clearly much more difficult for analysis and judgment. The procession of workmen through the iron and steel mill gates has changed in nationality time after time, but at all times the great mass of the labor has been composed of the more recent immigrants. For decades the American-born workman has been in the minority at the coke works and blast furnaces and in the iron and steel mills. The most cursory study shows it inconceivable that under present working conditions a change can occur in the direction of the American-born constituting a larger proportion of the working force in the industry. As the foreign-born die and the industry grows in size immigration must expand or working conditions must be changed so that American-born labor is attracted. Clearly it is a matter of serious import whether the United States should welcome to its shores increasing numbers of men who are content to do work which our own native born refuse to do. Apart from this sociologic aspect it is very pertinent to inquire, from the practical standpoint, whether it will continue to be possible for the industry to attract the immigration. With each of the countries which has in the past supplied us with so much of our population the movement to the United States has been more or less temporary. In turn, as conditions in their respective native lands improved, the men have been influenced to stay at home. Nor does it follow that if one emigrates he must come to the United States. In recent years there has been an important movement to South America, and year by year the amount of work which South America should and can do increases.

Whether the problem be to ensure a continuance of the flow of immigration for the maintenance of the iron and steel industry, by making the employment attractive, and at the same time make better men of the immigrants, or whether the problem be to attract American-born labor, the problem is a technical one, in that it involves the character of the service to be performed by the workmen and the conditions in which the service is performed. For this reason we included the technical as one of the different aspects in which the question of wages in the steel industry should be viewed, and in many respects the aspect is the most logical and promising. In the past few years the steel manufacturers have fully recognized the importance of improving working conditions, and encouraging a better home life. Millions of dollars have been spent along these lines and the disposition to effect these improvements grows as it is exercised. Despite these rapid improvements, however, the labor market has not been surfeited, but one finds rather that in recent years the periods of labor scarcity are more pronounced and the periods of unemployment are less marked, than was the case in the past.

It has been recognized by the sociological workers that seven-day labor, and apart from that twelve-hour-a-day labor, are undesirable from their standpoint, but a fact which these workers do not always recognize is that the workmen have opinions of their own. Not very long ago the United States Steel Corporation abolished seven-day labor in its plants, and the statement was made by Chairman Gary at the annual meeting of the stockholders April 20th that upward of 4000 men left the corporation's employ by reason of the change. The number of men who had been working seven days a week was not stated, but it is well known that it represented only a very small proportion of the total number of men employed by the corporation, so that the number of men who left must have been a very considerable proportion of the total number affected. There remains the twelve-hour day, with respect to a very considerable proportion of the men employed in the steel industry. As is well understood, the men do not actually labor during more than about two-thirds of the twelve hours during which they are technically on duty. There does not seem to be any particular reason why the service they perform should be reduced, but there are reasons which would make it advantageous for the work to be concentrated into a shorter period, whereby more time at home would be allowed. This is a technical question in works management. It has been very seriously considered already and is admittedly a very difficult one. It is a problem which must in nearby years be solved, though it certainly cannot be solved over night; but it is so important that the question of current wage rates cannot be approached without full reference to it.

---

## The Tango of the Electrochemists at the Chemists' Club

"And David danced before the Lord with all his might,—girded in a linen ephod."

We have often remarked in these columns that the great law of harmonic motion holds in other lines than that of pure physics. For example, the ebb and flow of material prosperity from boom times to hard times seems to follow with almost mathematical precision the same course as a pendulum. Individuals, too, are elated then depressed. Philosophy of one age is materialistic, of the succeeding age spiritualistic. So Fourier's series may be found to pervade the great world of men, women and things.

While it takes something more than Fourier's theorem to analyze any social change exactly, yet it must be apparent that the world now looks lightly on forms of amusement that formerly were condemned as vulgar, and the Puritanic notions of what is right and proper are being replaced by views Hellenistic in character. In short, the Greek pagan pantheistic idealism is being superimposed on our social structure. There are many evidences of this replacement. The prevalence of amateur and professional sport in daily interest, the freedom of dress that women are assuming, and finally the modern worship of Terpsichore that is increasing everywhere in the world are merely signs of the times. It was only a half a century ago that round dances were socially taboo and the advent of the waltz, polka and two-step was beset with vain remonstrances from society's mentors. This is remarkable but it is a fact.

The so-called modern dances growing so fast in popular delight are having a similar reception. They are, however, a perfectly natural concomitant of changes in other directions and have a clearly recognizable cause. This cause is natural physical relaxation that is needed after mental work. All intellectual or imaginative effort produces an effect on the sensory and motor centers of the brain. This is exerted harder and in more directions than heretofore because of intensity of modern thought. We can also adduce the theory that the thought centers of the brain are but glorified sensory or motor centers and that the former bear some relation to the latter as does the blossom of a plant to the leaf or as the cranium does to a vertebra. It was Goethe who pointed out first that the blossom was simply an extended and transcendental leaf and that the cranium was a development by functional evolution of the simple element of the backbone.

Accordingly, if we admit the theory that Goethe's discovery applies to the human brain, then on psychological grounds and also on physiological grounds, dancing of the tango or maxixe is due to the fact that the individual has had his thought centers greatly stimulated by many new things, and this calls for a balancing of his faculties by stimulation of the lower centers. Probably no better way for muscular exercise can be devised than dancing and probably in no way can the motor centers of the brain be better stimulated than by dancing. The great modern advances in thought, in art and in science produce marked effects on each and everybody's mind—mental displacements that, unless counterbalanced, can effect a permanent astatic mental condition. It is a rational procedure, therefore, to relax as in the present fashion in dancing, for the graceful movements of body to music produce a harmonic balance of motor centers and cause a normal return to equanimity. This is especially true if we admit the extension of Goethe's hypothesis of the glorification of an organ by its assuming a new function, for in that event the thought centers and motor centers are directly connected and no surer means of easing the former could be chosen than by easing the latter. Whether the modern dances are hurtful or vulgar depends entirely on how far the sex quality present in most forms of dancing predominates in both the conscious and unconscious mind, and that is entirely a question of individual self-restraint and good sense.

We can but admit, therefore, that the reaction from the Puritan notion that because a thing is pleasant, it is necessarily wrong, is a perfectly natural one and that the extension of human activity in a light and fantastic manner is normal and sound. The relation between dancing and religious activity as evidenced for example by the dancing dervishes or Shakers—"David danced before the Lord"—is a collateral line of thought. But what would the Calvinistic divines of the colonial period, such as Jonathan Edwards, have said to the tango or turkey-trot? Neither the sine curve nor signs of the times would have availed as an explanation to such worthies. The dance of the electrochemical scientists and engineers at the Chemists' Club would have been anathematized. But to them it was the charming finale of a glorious convention.

### A New Design of Filter Press

*To the Editor of Metallurgical & Chemical Engineering:*

Sir.—Having recently arrived from Australia, I have just seen the article in your February issue, entitled "A New Design of Filter Press," by Alfred Burger. If I understand the description aright, the same idea was put in practice at the Victoria Mill of the Waihi Gold Mining Company, New Zealand, when I was there in 1901. It was used to wash slime (200 tons per day) in Dehne and Martin filter presses after cyanidation, was invented by Mr. H. P. Barry, the superintendent, and was known as the "central wash." I believe it was also used at some of the mills at Kalgoorlie, Western Australia, about the same time.

### Value of Research Work

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—When the Wright brothers were experimenting with their gliders they were considered as "eccentric nuts" with a mania for flying. Nobody doubts now the fuuture commercial value or possibilities of the aeroplane.

Henry Ford was the target for ridicule in Detroit when he was "monkeying" with his first model. A few years later when cars were pretty reliable, although considered an expensive luxury, a very prominent business man was heard to remark that they might be a toy for the rich but they would never be used for trucking or other commercial purposes.

The above wellknown examples are typical of many other cases which have and will open fields of untold wealth to society. Many manufacturing institutions produce more wealth than gold mines for an equal amount of capital invested. This great earning power was made possible by the plodding research of some pioneer who single-handed had courage enough to venture out a little and match his starving along against his possible success. Then the miserly pittance that some of these same large firms give to further research work should shame their narrow grasping methods.

A prominent railroad after having been plundered time and again by financial pirates was in the receiver's hands. Then and not till then was an attempt made to improve the efficiency of the road. Now real road tests of the locomotives are being made by test cars placed between the locomotives and the train. The advice of the efficiency engineers will no doubt be followed and the earning power of the road will increase, the large as well as the small leaks will be stopped, and the road will get back on its feet again. Why should it be necessary for a railroad to get into a receiver's hands before steps are taken to increase the general efficiency and earning capacity of the road by employing efficiency engineers and experts to do research work?

A few of the larger concerns are spending many thousands to build and equip experimental laboratories to carry on experimental work along their particular line and find that it pays extremely well. Many others have contributed to The Mellon Institute of Industrial Research for scholarships. This manner of promoting investigation along new lines has proven very satisfactory to all concerned. For this method of providing means to carry on research work we are indebted to the foresight of the late Robert K. Duncan.

People are hunting to the farthest corners of the earth for radium bearing ore, especially since prominent authorities claim its value in the treatment of cancer. Thousands of dollars are being spent in this search and justly so. Money carefully spent in developing new industries or in improving old ones is likewise well spent and yields a wealth to society which cannot be estimated.

### The Technical Parasite

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Parasites are found in all walks of life and in all phases of human activity. They are as conspicuous in the technical world as elsewhere. The technical parasite is generally in the employ of a large manufacturing concern. He attends the meetings of scientific and technical societies, and even condescends to serve (?) on technical committees. While papers are being read or discussed he generally remains silent, seldom responding to an invitation to contribute to the discussion, more rarely still volunteering any information. His food consists chiefly of the crops laboriously raised by others and of this he partakes copiously and, if perchance he succeeds in raising a little himself, he guards it zealously for his own consumption. Notwithstanding this parasitic feeding, his attitude, instead of being one of humility and thankfulness, is often critical, not to say arrogant.

As a member of technical committees his work is seldom constructive. It is obvious that his interest in the labor of the committee ends when, in his judgment, it ceases to benefit him. He is secretive as to whatever information he has or fancies to have. While eager to receive, he is ever reluctant to give. He would even prevent the dissemination of knowledge likely to benefit others as it benefits him. He frequently affects to be the wise possessor of knowledge not available to the other members. This little game flatters his vanity.

What is there to be said in defense of the technical parasite? Certainly his vision is limited to the monetary value of his technical knowledge. He is unable to grasp the greater meaning, greater duty, and greater reward attached to a more lofty conception of the services owed by technical scientists to their fellow men. He apparently believes that he is serving the best interests of his employers—that his parasitic habits make him a more valuable man. In this egotistical attitude is he not misguided, even from a purely sordid point of view? To begin with, the exclusive knowledge he fancies or affects to possess is too often a mere *secret de polichinelle*. There are those who believe that a freer and more generous interchange of thoughts and information among technical men commercially engaged would promote progress in a way that must necessarily prove of much benefit to them. It is far from demonstrated that modern business, to be successfully conducted, is dependent on Chinese walls erected and guarded by technical parasites. It is now quite generally admitted that honesty is the best policy, in spite of the immediate returns which are seemingly within reach of the dishonestly inclined. Let us hope that the time will also come when the policy of free interchange of thought and knowledge will be recognized as the best policy by those sordidly inclined, in spite of the apparent gains to be derived from a parasitic policy.

Personally the technical parasite may be a very good fellow, but as a member of the great industrial, technical fraternity he is worse than useless. For my part, I should welcome the discovery and effective use of the exterminating bug that would put an end to his parasitic existence. X. Y. Z.

Cambridge, Mass.

### Central Research Organizations

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—The editorial re "Central Research Organizations" in your April issue prompts the comment that "research" being "invention," in its full development must utilize the strongest types of individuality, be controlled by personality and conducted by minds not essentially business.

The commercializing of the "research" idea as developed by personality may be possibly best conducted by a central organization, but the inventive ideas of great value can never be directed, controlled, or produced under organized effort. Invention is spontaneous like poetry, music and art.

Education helps, if not carried so far as to destroy originality.

Apparatus and finance are absolutely necessary especially in metallurgical work where volume is so necessary to prove or disprove a theory.

The same experiment may appeal to different minds very differently. The fact that one investigator sees only failure does not prove that another may not see success. It is best that the successful man does not know of all the failures of the unsuccessful or is not advised in the direction of his tests because of the failure of others.

Research can most efficiently be conducted under small units dictated solely by original personalities not connected in any way with commercial minds.

As results indicating industrial value are produced, the business mind or organization should take control, and it is to such organizations that research must look for all its finance, since its only product consists of merchandise that can be sold or utilized only by organized capital. To centralize research would be to suppress it in its highest development. However, the thought is unlikely of realization any more than the thought relative to the centralizing of poetry, music, or art.

### A New Source of Zinc Ore

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—The recent discovery of a deposit of calamine at Embreeville, Tenn., furnishes us with additional proof of the elusive nature of the silicate and carbonate ores of zinc.

The new deposits are found on the property of the Embree Iron Company, Embreeville, Tenn., 11 miles from the main line of the Southern Railroad, being reached by a branch line from Johnson City. This property has been worked in the past for the rich deposits of hematite which it contains. A blast furnace with a capacity of 200 tons was erected in the late '80's, and was in operation intermittently until 1908 when it was blown out.

Throughout the whole period of its activity it was known that the ore being fed into the furnace contained amounts of lead and zinc, though no one seems to have suspected the presence of any great amount. At times they experienced considerable difficulty in making the furnace function properly, partly due to the excessive amounts of zinc and lead in the burden.

The hematite was mined by hydraulic methods which partly explains the reason why such a small amount of zinc-bearing ore found its way into the charge, for the calamine lies underneath the overburden of soil and hematite.

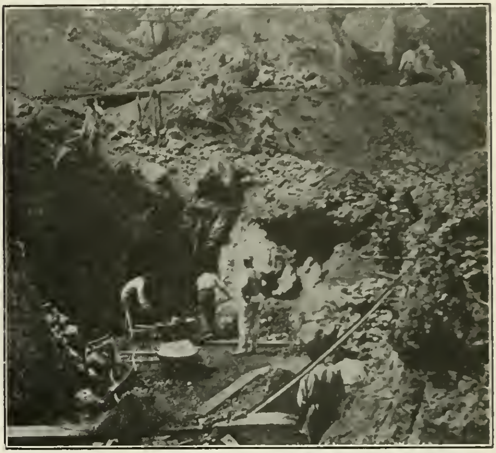

FIG. 1—OPEN CUT IN CALAMINE DEPOSIT, EMBREEVILLE, TENN.

Geologically the hematite and calamine lie in the Shady limestone, a Cambrian formation, along with the residual clays of the same formation, locally called "buck-fat." The calamine is found massive, that is, in lumps, in thin "stringers," and in granular form, all more or less mixed with the hematite-bearing soil, limestone, and "buck-fat." The associated minerals are hematite, galena, smithsonite and small amounts of cerussite and sphalerite, the latter mineral only in the limestone. The limestone is a dolomite, approximate $2CaCO_3.MgCO_3$.

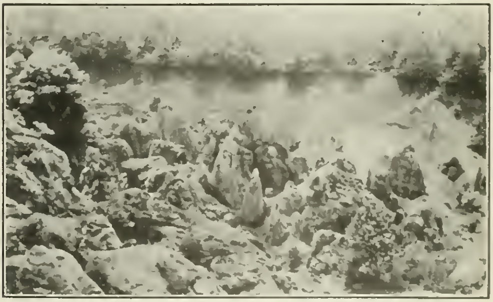

FIG. 2—ERODED PINNACLES OF SHADY LIMESTONE FORMED BY HYDRAULICKING FOR HEMATITE

The mining of the ore is carried on by means of open cuts and pits, the deeper deposits by tunnels and top-caving through "thunder-holes." The bottoms of the cuts have a gradient sufficient to allow tramming to be done by gravity.

The ore is hand-sorted in the cuts, the barren soil, limestone and clay being separated as far as possible from the zinc ore. The former products go to the "muck" pile, the latter to the washer to be treated. Temporarily the ore is being treated in a log-washer and a dry-house.

The mine cars run to a tipple on a trestle and dump on a grizzly with 3-in. spaces between bars, where it is washed with a spray from a nozzle. The oversize goes directly to the dry-house. The undersize discharges by chute into a 30-ft. double log-washer of the Longdale type. From the washer the washed material passes to a bucket elevator which discharges on a picking belt. The slimes pass to a slime pond.

On the picking belt the iron ore, limestone and country rock are picked, the zinc ore passing to a bin in the dry-house, from which it discharges to a tram-car and thence to the floor of the dryer.

The dryer is a structure 20 ft. by 120 ft., drying ore from 20 per cent to 5 per cent moisture at the rate of 30 tons per 24 hours. The finished product has the following approximate composition: Zinc, 33-38 per cent; iron, 11-15 per cent; moisture, 5-10 per cent.

## Blast Furnace Blowers

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In a very interesting article by Mr. J. E. Johnson, Jr., in the April number of this paper nothing is said about the use of the centrifugal compressor on the iron blast furnace. Mr. Johnson's many years as a practical blast-furnace operator entitles his opinion to especial respect. It has occurred to the writer that a brief discussion of the results obtained from this comparatively new style of blower, when operating on the iron blast furnace might be of interest. It seems to be conceded that the following points of contrast between centrifugal and reciprocating blowers may be set forth.

(a) Mechanical Efficiency.—This is much higher with the reciprocating type than with the centrifugal —probably 90 per cent or more with the former—while with the latter probably not much in excess of 70 per cent.

(b) The Volumetric Efficiency.—This is usually quite high in the reciprocating type, due to skillful design as indicated by Mr. Johnson. As a general rule, the volumetric efficiency is higher than the mechanical efficiency in a reciprocating blower. However, it is apparent that any leakage due to worn or cracked valves, etc., will easily reduce the volumetric efficiency. On the other hand, it is claimed that the *initial* efficiency of the centrifugal blower, while relatively lower, is maintained indefinitely, owing to the fact that there are no rubbing parts except the rotor bearings. A slight clearance is left between the impeller tips and the guide vanes.

(c) The Item of Inertia is Important.—Mr. Johnson has shown some of the reasons for engines "pounding." This is not a feature of the reciprocating type, necessarily, but it is harder to eliminate than with the centrifugal type which may be nicely balanced. The writer has seen a single-stage centrifugal blower delivering 40,000 cu. ft. of air per minute at a discharge pressure of 4 lb. per square inch, with coins balanced on edge, on the casing.

(d) Head Room.—The economy of space required for housing is greatly in favor of the centrifugal compressor.

(e) The "Over-all" or Net Efficiency of the Blower and Its Driving Unit.—The practice of using reciprocating blowers with internal-combustion engines has been generally adopted. Its advantages are apparent. The subject is ably discussed in detail elsewhere by Mr. H. J. Freyn[1] and others.[2]

With the centrifugal compressor it is necessary to use high-speed drive, viz., a motor or steam turbine, either necessitating the generation of electric power in the gas-electric generator, or else steam in the boilers, using the blast-furnace gas. In either event, thermal losses occur.

It has been stated that the economy of the steam turbine-driven centrifugal unit is enough higher to warrant its replacing gas-driven reciprocating blowers.[3]

While this may hold in certain special cases, it would appear to be doubtful as a general statement under present conditions.

Automatic regulation of blast volume is a feature of the centrifugal type which is attractive. The crux of the matter is an economic one and appears to lie with the question of the driving unit. The perfecting of a gas turbine with high thermal efficiency may place the centrifugal blower abreast of the reciprocating blower for blast-furnace work.

## The Western Metallurgical Field

### Brown Cyanide Process Decision*

In the issue of Metallurgical and Chemical Engineering for October, 1913, page 541, we commented on a decision of the United States District Court for the District of Delaware, in the case of Joseph A. Vincent vs. Tonopah Mining Co., et al. This suit was brought by Mr. Vincent as owner of patent 781,711, granted to Alden H. Brown Feb. 7, 1905, in which the patentee claimed invention of a process involving cyanidation followed by concentration. The Tonopah company was sued as infringing the patented process, and the District Court so held. Appeal was taken by the defendant to the United States Circuit Court of Appeals for the Third Circuit, which has reversed the original decree and remanded the case to the lower court with instructions to dismiss the bill for non-infringement.

Our comment at the time of the first decision was to the effect that we believed the patent could not be sustained in many cases, that it was of narrow application, and that its real import could not be gained until the case had been reviewed by a higher court. The Brown process was clearly defined as to certain successive steps in treating ores by cyanidation and concentration. * * * "First pulverizing the ore in the presence of cyanide solution; second, subjecting the ore to hydraulic classification by the introduction of cyanide solution at the bottom of an overflow tank to produce an ascending current; third, leaching the ore by the use of cyanide solution whereby the finer values of the ore are dissolved; fourth, removing the dissolved metallic values from the ore in any suitable manner; and finally, subjecting the residue of ore to concentration."

It appears that the process used by the Tonopah defendants involved crushing in cyanide solution, followed by concentration and subsequent cyanidation of the concentrates. Vincent sought to show that crushing in cyanide solution constituted essentially the cyanide treatment of ore by the defendant, and that the subsequent cyanidation of concentrates was an unimportant step, and that the process used was, therefore, essentially that of Brown. The Circuit Court of Appeals held differently, however: "After the defendant's concentration is finished the by-product goes forward to be subsequently treated by a protracted process of cyaniding. This is at variance with Brown's process in three respects; first, cyaniding follows concentrating (instead of preceding it); second, it is a system condemned by Brown and one he sought to avoid in that where 'concentration * * * is used preliminarily to the cyanide process it will be necessary to have a very extensive system of settling tanks in order to recover these suspended values and hold them in the mill so that they may be subjected to further treatment'; third, the defendant's process which physically withdraws from the operation of the process the products of concentration in advance of withdrawing those of cyaniding, makes the process one avoided by Brown, viz.: 'It is a well-known fact that the cyanide process recovers only the fine values, and in the treatment that I have devised these fine values are recovered by the cyanide process in the beginning, leaving only the coarser values, which are readily recoverable by concentrating, the latter being specially adapted for saving this class of values.' It is apparent, therefore, that the defendant's device, which the proofs show has been of great practical worth, owes its worth to the fact that it is built and operated in express disregard to the instructions of Brown's patent. Without passing on the question of the validity of that patent, it suffices to hold defendants do not infringe."

[2] "Gas-driven Blowers at the Bethlehem Steel Co." Abstract of paper read before the Am. Iron and Steel Institute—see *Iron Trade Review*, June 19, 1913.

[3] L. C. Loewenstein, "Centrifugal Compressors," *General Electric Review*, March, 1912.

*See also the article on page 219 of our April issue.

Other extracts from the decision, showing the reasoning of the court, are interesting: "It will be noted that no new principle of operation, either in cyaniding or concentrating themselves was disclosed in this patent. It was at most simply a more effective treatment and it will thus be seen that transposition of concentration from initial to final stage, and of cyaniding from final to initial stage, is the substantial disclosure of this device. * * * This two-staged process—first cyaniding, next concentrating—being the only disclosure of Brown and the claims embodying those two separate, individual, completed stages or steps, it follows that any process which makes concentration an intermediate and completed step, one that precedes final and effective cyaniding, is a process different from the one Brown disclosed and claimed. * * * The defendants, in common with Brown, it may be conceded, are using the cyanide solution in the earlier stage of their process, and to that extent we may say initially utilize the general chemical treatment incident to cyaniding, preparatory to concentrating. But beyond this the resemblance ceases, for by defendant's process concentration * * * is the initial and intermediate step in their process."

## Company Reports

The seventh annual report of the **Goldfield Consolidated Mines Co.**, for the calendar year 1913, gives the following data on operation: The mines produced 349,465 tons of ore, of which 330,217 tons of an average gross value of $14.88 per ton was milled, and 19,248 tons of an average gross value of $27.39 per ton was shipped. The total gross value was $5,438,853. Deducting metallurgical losses, smelter discounts and the cost of a small tonnage purchased, an aggregate of $496,025, the value realized from the year's operations was $4,942,828. Expenses of mining, milling, transportation, construction, taxation and general expense amounted to $2,210,883, leaving a net realization of $2,731,945. Operating cost per ton was 54 cents lower than for the previous annual period. Two dividends were paid during the year, one for 30 cents per share and one for 40 cents, aggregating $2,491,404. At the close of the year the company's cash balance is $1,074,372, with bullion and miscellaneous products settlements outstanding of $161,217. The net realization from operation was 50.23 per cent of gross value of ore.

The report contains many detailed costs of operation, from which we take the following:

### Segregaton of Milling Costs

*Per Ton of Ore Milled*

| Department | Labor | Supplies | Power | Total | % Total |
|---|---|---|---|---|---|
| Crushing and conveying... | $.017 | $.008 | $.005 | $.033 | 2.08 |
| Stamping | .032 | .028 | .065 | .125 | 7.73 |
| Chilian milling | .018 | .033 | .046 | .097 | 6.07 |
| Elevating and classifying.. | .012 | .004 | .006 | .022 | 1.36 |
| Tube milling | .014 | .101 | .107 | .222 | 13.93 |
| Concentration | .040 | .007 | .016 | .063 | 4.00 |
| Neutralizing | .007 | .048 | ... | .063 | 3.46 |
| Settling | .013 | .049 | ... | .062 | 3.86 |
| Dissolution | .021 | .363 | .034 | .418 | 26.23 |
| Filtering | .038 | .025 | .013 | .076 | 4.78 |
| Tailing expense | .001 | ... | ... | .001 | .09 |
| Assaying | .003 | .019 | ... | .022 | 1.39 |
| Precipitation | .008 | .055 | .012 | .075 | 4.68 |
| Refining | .023 | .041 | ... | .064 | 4.05 |
| Water | .005 | .066 | ... | .071 | 4.47 |
| Surface and plant | .011 | .005 | ... | .016 | .97 |
| Steam heating | .003 | .007 | ... | .010 | .60 |
| Storehouse and office | .012 | .003 | ... | .015 | .94 |
| Stable | .001 | .001 | ... | .002 | .12 |
| Watchmen | .024 | ... | ... | .024 | 1.52 |
| Superintendence and foremen | .059 | ... | ... | .059 | 3.72 |
| Lighting | .002 | .002 | .014 | .018 | 1.22 |
| General expense | .003 | .005 | .001 | .009 | .55 |
| Mill tools | .001 | .001 | ... | .002 | .07 |
| Electrical department | .003 | .003 | ... | .006 | .33 |
| Pumping battery water | .005 | .002 | .015 | .022 | 1.34 |
| Experimental | .005 | .002 | ... | .007 | .44 |
| Totals | $.381 | $.878 | $.337 | $1.596 | 100.00 |
| Per cent of total cost of milling | 23.90 | 54.99 | 21.11 | 100.00 | |
| Per cent of combined cost of milling and concentrate treatment | 19.35 | 44.59 | 17.12 | 81.06 | |

### Segregation of Concentrate Treatment Costs

*Per Ton of Concentrate Treated*

| Department | Labor | Supplies | Power | Total | % Total |
|---|---|---|---|---|---|
| Raw cyanidation | $.095 | $.561 | $.185 | $.841 | 15.11 |
| Filtering and conveying | .230 | .045 | .040 | .315 | 5.66 |
| Roasting | .223 | .529 | .102 | .854 | 18.03 |
| Acid treatment | .118 | .403 | .173 | .694 | 14.65 |
| Tube milling | .028 | .018 | .043 | .089 | 1.87 |
| Cyanidation of roasted product | .085 | 1.077 | .138 | 1.300 | 27.42 |
| Assaying | .016 | .127 | ... | .143 | 2.57 |
| Precipitation of copper | .024 | .002 | ... | .026 | .54 |
| Precipitation | .014 | .091 | .019 | .124 | 2.23 |
| Refining | .038 | .069 | .001 | .108 | 1.93 |
| Disposal of tailing | .026 | .017 | .008 | .051 | 1.07 |
| General expense | .015 | .011 | ... | .026 | .47 |
| Handling dump | .065 | .010 | .002 | .077 | 1.63 |
| Water | ... | .323 | ... | .323 | 6.82 |
| Totals per ton of concentrate | $.977 | $3.283 | $.711 | $4.971 | 100.00 |
| Totals per ton of ore | 0.72 | .248 | .053 | .373 | |
| Per cent of total cost of concentrate treatment | 19.65 | 66.04 | 14.31 | 100.00 | |
| Per cent of combined cost of milling and concentrate treatment | 3.66 | 12.59 | 2.69 | 18.94 | |

The report states that experiments are being continued looking toward means of successfully treating large quantities of low-grade ore that cannot now be mined and treated at a profit. No process has yet been devised to meet this need. In regard to tailings that have been impounded since the beginning of operations, careful experiments have shown that this material can be subjected to further treatment at a profit of a few cents per ton. Plans for equipment to handle the tailings are practically complete, and will be executed at the proper time. About five years' time will be required to treat the accumulation.

The constituent companies of **Phelps, Dodge & Co.** enjoyed uninterrupted operations during 1913, and produced more copper than in any previous year, according to the annual report for that period. Copper ores mined amounted to 1,978,892 tons, of which 1,122,372 tons was concentrated and the balance smelted direct. The quantity of copper produced was 155,665,712 lb., containing 31,141 ounces gold and 1,870,162 ounces silver. Details of operation of constituent companies are as follows:

The reduction works department of the **Copper Queen Consolidated Mining Co.** treated 1,193,726 tons of copper-bearing material, producing 133,410,592 lb. copper, 1,870,162 ounces silver and 31,141 ounces gold. Experiments on dust losses from the large steel stack showed that copper loss had been reduced from a daily average of 14,310 lb. in 1909 to 2286 lb. in 1913, with practically the same number of furnaces and converters in operation. The two tests were taken in the same month and under similar weather conditions. In the blast-furnace department the flue dust produced was 3.92 per cent of the charge, as against 5.9 per cent in 1912 and 7.59 per cent in 1911. Furnace charge per day was 343.5 tons, of which 12.4 per cent was coke. Matte fall was 18.79 per cent. In the reverberatory department the McDougall roasting furnaces produced 56.5 tons of calcines per furnace per day, and flue dust to the extent of 5.2 per cent of the charge. Reverberatory furnaces smelted 289.6 tons per furnace per day. Oil consumption was 0.9 bbl. per ton of charge, of which 34.57 per cent was charged to steam and credited to reverberatories. Basic lined converters were used entirely throughout the year, treating 206,493 tons of matte and producing 67,256.6 tons of bullion from an average of 6.5 stands per day. In the power plant the cost per horse-power for the year was $54.844, and the average daily horse-power developed was 4595.8.

"During the year an experimental plant was completed, and experiments were conducted principally with the view of determining the best method of leaching low grade ores and the tailings from the concentrators. A Wedge furnace, of the muffle type, was erected, which produced calcines containing a very high proportion of their copper soluble in water, and practically all of the remainder soluble in dilute acid, but with a high fuel consumption.

"The recovery of the dissolved copper was effected by electrolysis, using graphite anodes, and reducing the resistance and increasing the yield of sulphuric acid, by injecting sulphur dioxide into the electrolyte. The results were favorable, but several problems which presented themselves, as the experiments progressed, remain to be solved, as well as a reduction of the high fuel consumption, before definite conclusions can be reached."

**The Detroit Copper Mining Co. of Arizona** reports the treatment of 537,324 tons of copper-bearing material during 1913, with a yield of 22,255,130 lb. of copper bullion, at a rate of 41.42 lb. of refined copper per ton of ore. The average grade of all ore mined was 2.9 per cent copper, compared with 3.25 per cent for 1912. Concentrating ore averaged 2.78 per cent copper, compared with 3.08 per cent for 1912.

Concentrating operations are epitomized as follows:

| | |
|---|---|
| Ore concentrated, 517,518 tons, assaying | 2.785% cu. |
| Concentrates produced, 66,928 tons, assaying | 15.834% cu. |
| Savings—Ore and concentrates | 73.52% |
| Ore and tailings | 75.18% |
| Concentrates and tailings | 74.76% |
| Assay only | 75.27% |
| Tailings assay | .79% |
| Tons ore milled per ton concentrates | 7.73 |
| Actual running time to total time | 95.46% |
| Ore milled per 24 hours actual running time | 1485.14 tons |
| Water used per ton ore milled | 554.98 gal. |

The smelting plant has been thoroughly overhauled and basic converting has replaced acid practice. At the power house a new boiler, steam turbine, Nordberg compressor and condensing plant were installed. A new furnace, flue, dust chamber and furnace building were erected.

Concentrator operations of the **Moctezuma Copper Co.** were as follows:

| | |
|---|---|
| Ore milled | 603,654 tons, dry weight, assaying 3.557% cu. |
| Concentrates produced | 135,057.331 tons, assaying 13.376% cu. |
| Tailings produced | 468,596.669 tons, assaying 0.67 % cu. |
| Saving (average, four methods of figuring) | 85.0% |
| Ratio of concentration | 4.469 |
| Tons of ore milled per day, actual running time | 1743.729 |
| Fresh water used per ton of ore milled | 1020.721 gal. |

The cost of milling was slightly higher than in 1912, due to changes and repairs made in the mill.

**The Burro Mountain Copper Co.** reports an addition of about 50,000 tons of 2.35 per cent copper ore to known reserves. A favorable site for a concentrator of 1000 tons daily capacity has been chosen about 3 miles easterly from Tyrone. A central power plant, equipped with two 1000-hp Diesel engines, will be situated at Tyrone.

The fifteenth annual report of the **American Smelting & Refining Co.**, covering the calendar year 1913, shows that after charging off $1,525,518 for depreciation of property, and paying the usual dividends on preferred stock, the surplus income for the year was $3,736,541, of which $2,000,000 was paid to holders of common stock. The earnings from smelting and refining works and from mines are $3,570,532 less than during 1912. This decrease arises largely from the fact that ore mined from the company's properties, and awaiting transportation facilities, is valued only at cost of mining. A large credit of this character has been deferred awaiting normal conditions.

The company carries on its pension fund forty employees whose days of usefulness have passed. The income from the pension fund exceeded payments during the year by $10,395.

To promote fair treatment and cordial relationship between the company and its employees, the services of Hon. C. P. Neill, formerly Labor Commissioner of the United States Government, under the Roosevelt, Taft and Wilson Administrations, were secured in May, 1913, and the welfare work, hospital arrangements and employer's liability settlements of the company have been placed under the supervision of a committee, of which Mr. Neill is chairman.

## The Iron and Steel Market

April has been a month of negative rather than positive developments in the iron and steel trade. The dullness which began late in February and reached an acute stage in March was almost universally expected to give way to more active conditions in April, a month marking the general inception of outdoor work and also a time by which the stocks accumulated by reason of the fairly heavy buying of January and early February should be exhausted.

The month, however, brought no improvement whatever in the iron and steel markets. In most quarters the feeling has been, on the contrary, that a great deal of ground has been lost. Close analysis indicates that there has been less of actual loss than there has been failure to attain what was expected. The current concepts of the state of trade are colored in pessimistic vein. This is illustrated by the fact that the rate of operation of the steel mills is frequently stated in current talk at less than the actual rate. There is excellent ground for an estimate that the steel industry as a whole has operated during April at fully 65 per cent of its full capacity, whereas statements have sometimes been made, and have gained considerable credence, that the industry has not been operating at more than 50 per cent. The reduction in mill activity has therefore not been large, for it is doubtful whether at any time in February a rate of more than about 75 per cent was attained.

The course of steel prices has been downward, though not radically so. A very low level was reached in December, forming the basis of the buying movement which began in that month and hardly lost its force until February was well advanced. Prices rose but slightly, and they have correspondingly declined but slightly, the level to-day being substantially the same as at the recent low point.

The outlook is extremely difficult to discern, and opinions now expressed by usually competent judges seem to be colored largely by individual temperament. Thus there are those who view the low rate of buying, a rate even below the lessened rate of producing and shipping, and conclude that the trade is booked for worse times, lower prices and lesser production than has yet been seen, while there are those others who reason that the buying has been abnormally low, below the actual rate of consumption, that everything bad has been "discounted' and that the market cannot grow worse. Hence they insist it must grow better.

For a time the steel industry embraced the view that a decision in the eastern freight rate case (now expected for about the middle of May) or possibly even an unfavorable decision, would be followed at once by a very considerable expansion, through buying not simply by the railroads but by other consumers as well, but lately this view has been in process of abandonment. The inception of spring has brought no improvement, and now hopes are beginning to center upon crop prospects, which are favorable and which are expected to become the subject of more detailed and precise information and prediction as the weeks pass. It is admitted at last that no improvement such as would operate the steel industry at capacity can possibly occur before September or October, while as to operations in the next two months the chances are about even for an increase or a decrease.

### Pig Iron

Transactions in pig iron were very light in April, lighter even than in March. In many cases consumers reduced their requisitions against contracts, and such action coupled with extremely light buying has placed the furnaces in less comfortable position. Furnacemen have not, however, displayed any disposition to cut prices, their firmness in such circumstances being rather unusual. The American Pig Iron Association, formed January 8, may be partly responsible for the indisposition to cut prices, since while the association involves nothing by way of price agreement it has done much towards disseminating information as to production costs, which are alleged to be above selling prices, and has thus encouraged sellers to avoid cutting. Price changes in the month include advances of 50 cents at Cleveland and 25 cents at Buffalo and a decline of 25 cents in the southern market, so that the average level of prices is substantially unchanged, being, however, nearly 50 cents a ton above the low point late in January. Current prices are as follows: No. 2 foundry, f.o.b. Birmingham, $10.50; delivered Philadelphia, $15; f.o.b. furnace, Buffalo, $13.50; delivered Cleveland, $14.25; f.o.b. furnace, Chicago, $14.25; at valley furnaces (90 cents higher delivered Pittsburgh): Bessemer, $14; basic, $13; malleable, $13 to $13.25; No. 2 foundry, $13.25; gray forge, $12.75.

### Steel

As forecasted in the report a month ago, the billet and sheet bar market has failed to advance $1 a ton as of April 1 through mills having been quoting $21 on billets and $22 on sheet bars for first quarter, and $1 advance over these figures for second quarter delivery. On the contrary, the highest that could be quoted as the market is $21 for billets and $22 for sheet bars, at maker's mill, Pittsburgh or Youngstown, while it is believed in many quarters that these figures could be shaded $1 a ton on any active inquiry. There has been no demand, however, and it is evident that mills covered quite generally for second quarter as well as first quarter when the market was at about $20 for billets and $21 for sheet bars, late in December and early in January. Forging billets are $25 to $26 and rods $26, Pittsburgh.

### Finished Steel

Finished steel products have shown a declining tendency. Plates, shapes and bars have definitely dropped to 1.15c, and even relatively small lots can be secured at this level, which represented the extreme of the decline in December. Steel pipe was reduced one-half point, or about $1 a ton, through the new card issued April 20 by the National Tube Company, this change restoring the discounts in effect prior to the half-point advance of February 2. Line pipe was likewise reduced April 20. The sheet market has steadily softened.

Prices named below are f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.15c.

Shapes, 1.15c.

Steel bars, 1.15c., base.

Iron bars, 1.30c., Pittsburgh; 1.22½c., Philadelphia; 1.12½c., Chicago.

Wire nails, $1.60 per keg, base; plain wire, 1.40c., base.

Sheets, blue annealed, 10 gage, 1.40c.; black, 28 1.85c. to 1.90c.; galvanized, 28 gage, 2.85c. to 2.90c.; painted corrugated, 28 gage, 2.05c. to 2.10c.; galvanized corrugated, 28 gage, 2.90c. to 2.95c.

Merchant steel pipe, ¾ to 3 in., 80 per cent off list.

Steel boiler tubes, 3½ to 4½ in., 71 per cent off list.

Standard railroad spikes, 1.40c. to 1.45c., Pittsburgh; 1.50c., Chicago.

Structural rivets, 1.70c.; boiler rivets, 1.80c.

Cold rolled shafting, 64 to 65 per cent off list.

---

## The Possibilities of St. Louis as a Field for Electrochemistry

Mr. C. F. Carrier, Jr., of the firm of Lawrence & Carrier, Inc., consulting chemical engineers of St. Louis and Memphis, lectured on the above subject on April 14 before the League of Electrical Interests in St. Louis in a most interesting manner.

He first sketched to what extent electrochemical industry already exists in St. Louis. "Electroplating is already old and will increase or diminish from other than electrochemical reasons. The laundries are making some bleaching liquor on a small scale for their own use by passing direct current through a solution of common salt. One plant for the production of oxygen and hydrogen gas is already in operation and a second one will be in use in the very near future. Sporadic attempts have been made to use the electric furnace for steel and brass, but it is only recently that a real steel furnace has been contemplated and will very soon be in operation.

"The location of an electrochemical enterprise is, of course, governed by the same general principles that apply in the location of any industry. The final test is will it pay? The most prominent factor is the power cost, but in many cases the less obtrusive factors have not been given due emphasis. Power is never the whole cost and in many cases industries classed as electrochemical, this factor will be less than 25 per cent of the manufacturing cost. It is but natural to contrast our situation with Niagara Falls and New York, the two great electrochemical centers of the country and see to what extent the various factors have determined the fixing of certain industries at these points.

"The first Niagara power was delivered August 26, 1895, and the power company was confronted with the problem of disposing of the largest single block of power that had ever been put on the market at one time. They soon found that the regular industries of the district would never be able to absorb so much power; therefore it became necessary to offer power at extremely low rates in order to stimulate the creation of new industries that could use large blocks of power. The effort was successful, and we now see the great industries that have made Niagara the great electrochemical center of the world. This power was offered at rates with which St. Louis can never hope to compete, but at the present time this power has been almost entirely absorbed, and the tendency of the rates has been steadily upward. There is still a small amount of power to be had right at Niagara Falls at rates somewhat better than are offered here in St. Louis, but the difference is rapidly disappearing and we find that at Buffalo the rates are really higher, as shown by contract forms from Buffalo and St. Louis in my possession and the terms of contract are favorable to St. Louis, as the Buffalo contract stipulates such a high rate during the peak hours that the average price per kilowatt for 24-hour service would be materially increased.

"For large blocks of power with a high load factor a very good rate can be obtained in St. Louis. An electrochemical plant would operate 360 days per year, and under proper management should be able to maintain a load factor of 85 per cent. On a basis of 50 kw the net cost per kilowatt hour in St. Louis for prime power would be 7¼ mills. This figure only applies to large blocks of power with a high load factor such as would be the condition in an electrochemical plant. For larger loads an even better net cost is obtainable. For other manufacturing purposes the power rates at practically all points in the country are on a competitive basis with steam-driven plants, and owing to its cheap supply of fuel St. Louis has a great advantage over Buffalo.

"The figures discussed above are based on power purchaser from central stations. It will be interesting to know what can be done with the isolated plant. Central station managers have been slow to realize what extremely economical results have been obtained in the power plants of some of the electrochemical plants, especially in the copper refining industry. Near New York City, with coal costing more than 100 per cent higher than at St. Louis, plants of over 10,000 kw are delivering power at the switchboard, and this is refined power direct current, at 6 mills per kilowatt-hour. This figure can nearly be duplicated at East St. Louis with a 1000-kw plant operating 360 days per year with an 85 per cent load factor and a 10,000-kw plant would give a figure of 5 mills. Such a plant is not a chimera, for there are single electrochemical industries taking from 10,000-40,000 kw.

"The central station manager has also been slow to realize the possibilities of adjusting a heavy off-peak load to balance the load factor of the station. An electrochemical plant having a normal demand of 1000 kw could be arranged to take 25-35 per cent overload during the off-peak hours. Practically every station has a large amount of idle apparatus during at least 16 hours per day, and usually longer. This power, taken only above the normal demand and only during off-peak hours, could be sold profitably at a very low price, and the effect would be to raise the load factor of the power plant and to diminish the net cost per kilowatt-hour to any consumer who could meet the load conditions specified, say a load factor of over 80 per cent.

"Those industries in which the cost of power is an overwhelmning factor in the cost of production must of necessity go to the cheap power. Nitric acid is made from the atmosphere in Norway by high-tension electric arcs, and pig iron is made in California in an electric furnace, but even Niagara cannot compete with either. Calcium carbide, carborundum and graphite are for the time at least beyond the reach of St. Louis competition, and we shall probably continue to see aluminum oxid made in East St. Louis shipped to Niagara and Massena Falls and the finished metal shipped back to St. Louis, but this does not prove that there is no hope for St. Louis in the electrochemical field.

"When the ratio of power cost to selling price begins to diminish, as is the case with many of the other electrochemical products, the increasing importance of other factors will soon counterbalance even a substantial power cost difference, should such exist. A few examples will show this very clearly; 70 per cent of the world's production of copper is refined in the New York manufacturing district with steam power that in times past at least has been 50 per cent higher than at Niagara. Electric steel is being made in all parts of the world with energy from all types of prime movers and at prices ranging from $10-$150 per horsepower per year. Most of the electrolytic caustic soda and bleach made in Europe is with steam-driven power plants, and there are two such plants within a few miles of New York City operating profitably and using power that costs over 100 per cent higher than the St. Louis central station rate for the same power conditions.

"Assuming caustic soda to be manufactured at St. Louis, about 25-35 per cent of the manufacturing cost will be power. This cost would be approximately $20 per ton of finished caustic, charging all the power to the one product. At the rates which the caustic plants were able to obtain at Niagara when they started, the advantage would be about $9 per ton against St. Louis. This puts the situation in the most unfavorable light possible, but even so, competition is well within the bounds of commercial possibility. Cheaper fuel for evaporation of the product amounts to $1.50, the saving by distributing locally in tank cars instead of reducing to a solid saves $3 in containers, labor and fuel, lower freight to natural market might amount to $3-$5 per ton, hence there is a large natural market within the bounds of which a St. Louis plant would have a substantial advantage over Niagara and Michigan points.

"One of the most alluring fields for St. Louis is in the melting of steel, copper, brass and other alloys."

Among other electrochemical possibilities Mr. Carrier mentioned that St. Louis alone purchases upward of $50,000 worth of barium peroxide per year from England, yet St. Louis has barium sulphate rock almost at its door. This can be reduced to over 90 per cent soluble condition in an electric furnace, while only 60 per cent becomes soluble in a fire furnace. The author concluded with the expression of his firm belief in the electrochemical possibilities of St. Louis.

---

**The production of aluminium ore** in the United States in 1913 amounted to 210,241 long tons, valued at $997,698. This is an increase of 31.5 per cent in quantity and 29.8 per cent in value as compared with 1912. Alabama, Arkansas, Georgia and Tennessee were the producing states.

# The Development of Copper Leaching and Electrolytic Precipitation at Chuquicamata, Chile[1]

BY E. A. CAPPELEN SMITH

The Chuquicamata copper mine is located at Chuquicamata, a station on a branch of the Antofagasta and Bolivia Railroad, in the Province of Antofagasta, Chile, between 22 and 23 degrees South latitude. Chuquicamata is 165 miles by railroad from Antofagasta, and 82 miles in a straight line from the coast and lies at an altitude of 9500 ft. above sea level.

The deposit has long been known as the atacamite deposit of Chile, and for many years past has been mined by the natives. As evidence of their operations we find in the old workings many stone utensils, hammers, etc.—and mummies.

The deposit is a brochantite mineral contained in the cleavages of the granodiorite, mixed in part with chalcanthite and to some extent with atacamite, and with a deposit of salt. A small amount of caliche containing nitrates is also present in the upper layers of the ore-body.

The so-called Llampera ore body extends for a distance of approximately 8,000 ft. with an average width of about 500 ft. Throughout the whole length of the deposit numerous tunnels have been run and a very large quantity of ore has been left on the dumps from these tunnels. From the tunnels raises have been made almost to the surface, leaving in places a shell over the workings 8 to 12 in. thick. A few shafts have also been sunk in the ore deposits, the deepest one to a depth of 110 meters.

## Acquisition and Development of the Property

The property was acquired by Mr. Albert C. Burrage of Boston, who, in connection with the firm of Messrs. M. Guggenheim's Sons, formed the Chile Exploration Company, which company now owns the property.

The property has been explored by churn-hole drilling. The drilling has developed an ore-body in excess of 200,000,000 tons. Most of the drill holes, however, were stopped while the bottom of the hole was still in ore.

The general direction of the ore body is north and south. Lately a number of drill holes have been sunk at a considerable distance west of the Llampera, and after going through from 300 to 400 ft. of capping, chalcocite and chalcopyrite have been encountered, giving indications of a very materially increased tonnage over that reported up to date.

In the Llampera zone, of the 200,000,000 tons of ore so far developed, approximately two-thirds is brochantite and one-third sulphides. No change in the formation has been shown, even in the deepest drill holes, the ore still appearing to be in the cleavages of the granite. The lower drill holes show primary ore. From the amount of ore developed and indicated, it appears that the Chuquicamata mine is probably the largest copper deposit known to-day.

It was generally assumed that this large and well-known deposit of ore was atacamite, and as such could not be treated at a profit by any of the established methods; first, on account of the highly siliceous nature of the ore and the absence of sulphides and water, and, secondly, on account of the volatilization in smelting of the copper chloride.

It was demonstrated that the mineral was not atacamite (oxy-chloride) but brochantite (oxy-sulphate) and that mixed with the brochantite in the upper parts of the ore-body was a deposit of salt. The brochantite, being an oxy-sulphate of copper, is insoluble in water but very readily soluble in dilute sulphuric acid. It was, therefore, evident that the way to treat the brochantite ore-body would be by wet methods.

## Preliminary Experiments

About 600 tons of the oxidized ore, representing, as near as we can judge, a fair average of the oxidized ore-body, have been shipped to New York for experimentation on a small scale.

At first tests were run on a very small scale and gradually, as promising results were obtained, on a somewhat larger scale, treating about 2 tons of ore per day. The average content of the ore thus treated was somewhat in excess of 2 per cent in copper.

The main problems which presented themselves for solution were:

1. The solubility of the copper minerals in sulphuric acid.
2. The amount of chemicals required as a dissolving agent.
3. The amount of impurities which would enter the solutions, and
4. The precipitation of the copper from the solutions obtained.

The principal developments in the solving of these problems may be briefly summarized as follows:

1. **Solubility of the Mineral**—Experiments conducted on a small scale disclosed the fact that the copper-bearing mineral was very readily soluble in a cold dilute sulphuric acid solution and that only comparatively coarse crushing would be required.

2. **Chemicals Required**—After prolonged experimentation, it was found that the ore yielded enough sulphuric acid, from the decomposition of the copper sulphate present in the brochantite, to more than make up the losses in sulphuric acid in the operation. The losses of acid occur mainly in two stages: first, the loss due to dissolving other components besides copper from the ore; and, second, due to wasting of solutions through discarding of the residues.

3. **Impurities Entering the Solutions**—Experimentation extending over a long period of time has shown that no deleterious amount of impurities will accumulate in the solution, other than the chlorine derived from the salt deposit mixed with the mineral in the upper parts of the ore body.

4. **Precipitation of the Copper**—The experiments conducted in our experimental plant have shown conclusively that electrolytic copper of the highest grade can be produced from the sulphuric acid solutions obtained.

## Experimental Leaching

After completing a number of leaching tests on a laboratory scale, and after running a number of tests each with 100 kilos of material, experimentation was inaugurated on a larger scale and a plant was built of sufficient size to treat two tons of ore per day.

In this plant there have been treated 131 charges of ore and the plant has been run entirely as a self-contained unit—leaching the ore, washing it, purifying and electrolyzing the solutions obtained, and leaching the following lots of ore with the electrolyzed solution from previous charges.

In this plant were treated ores representing the general character of the oxidized ore body at Chuquicamata; some high in copper, others low in copper; some high in impurities, others low in impurities, and enough runs were made to prove the method on both high and low-grade ores, and on ores containing large amounts of salt as well as smaller amounts of salt, this being the principal impurity in the ore-body. The salt deposit, however, is confined to the upper 50 ft. of the ore-body and principally to the first 25 ft.

---

[1] A lecture delivered at the 25th General Meeting of the American Electrochemical Society, Columbia University, New York City, April 18, 1914.

In order to make sure that the method should be tested under the most adverse conditions, the same solution was used over and over again for the treatment of the before-mentioned 131 charges of ore, only setting aside enough solution to allow for the excess acid. A complete analysis of this solution was then made and showed the following contents:

| | Grammes per litre |
|---|---|
| Cu | 50.44 |
| Fe | 3.71 |
| Mn | 0.07 |
| P | 0.06 |
| As | nil |
| Sb | nil |
| CaO | 0.80 |
| MgO | 3.32 |
| $Al_2O_3$ | 1.61 |
| $Na_2O$ | 21.60 |
| $K_2O$ | 5.00 |
| $SO_3$ | 122.75 |
| Cl | 11.52 |
| Free acid (as $H_2SO_4$) | 28.00 |
| Total solids on ignition | 189.40 |
| Nitric acid | 4.00 |

The results obtained when using the solution which had previously treated 131 charges of ore were just as good as the results with the solution made from sulphuric acid and water. In other words, the accumulation of impurities has been proven to have absolutely no effect whatever on the results of the leachings obtained. The average extraction obtained in this 2-ton plant was 90.99 per cent.

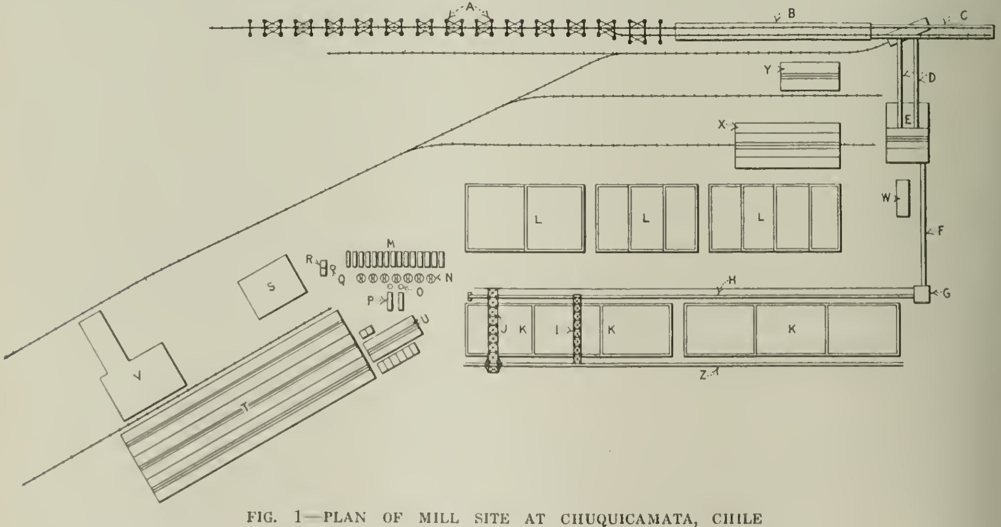

FIG. 1—PLAN OF MILL SITE AT CHUQUICAMATA, CHILE

Following the experiments in the 2-ton plant, a leaching tank was built of concrete, lined with mastic asphalt, having a cross section of 4 ft. x 6 ft. and 15 ft. deep, holding 15 tons of ore, this allowing the use of the full height of ore column since adopted for the plant now building at Chuquicamata. The question to be decided was whether it was feasible to leach the ore in tanks of this depth. Extensive experimenting gave results confirming those obtained in the smaller tanks.

A wooden filter-bottom with cocoa-matting on top has been employed in the 2-ton tanks and in the 15-ton tank, although a great number of leachings were made without any filter-bottom, simply placing a piece of cocoa-matting over the out-flow pipe.

All leachings were made without applying any extraneous heat.

The washing of the ore was by the so-called "piston" method, with a final water-wash, and the tailings, or residues, discharged contained an average of about 12 per cent moisture, and about 0.04 per cent water-soluble copper.

### Extractions Obtained

The leaching results obtained up to date are as follows:

| | |
|---|---|
| The average extraction while treating the ore in lots of 100 kilos each was | 90.62 per cent |
| The average of 131 charges treated in the 2-ton plant shows an extraction of | 90.99 per cent |
| The average extraction obtained in the 15-ton tank, while treating 25 charges leached up to date, has been | 90.96 per cent |

These results being based on the weight and sampling of the ore as charged into the tanks and the weight and sampling of the residue discharged from the tanks.

By combining all of these leachings and taking the copper contents based on the weight and sample of the ore treated, as against the copper produced in the electrolytic tanks in the form of cathode copper, together with the copper held in solution as copper sulphate, the extraction was 89.6 per cent. The small discrepancy is accounted for by solutions, of which no account has been taken, which have been removed for special tests, as well as spills which will necessarily occur in operating a small scale plant.

### Amount of Chemicals Required

After having supplied the amount of sulphuric acid required to start the operations, it was found that not only was no further acid required, but that excess acid was produced from the sulphuric acid contained in the ore itself, to such an extent that an actual gain is shown of approximately 9 pounds of acid ($H_2SO_4$) per ton of ore treated. In other words, it will be necessary to discard an amount of solution equivalent to this gain in acid in order to prevent the acid from accumulating in the process. This gain in acid was made while treating an ore averaging a great deal higher in salt than even the average of the upper layers of the ore body at Chuquicamata will show. As the greatest loss of acid is in forming sodium sulphate, I believe that a still larger gain in acid will be shown when treating the average ore body.

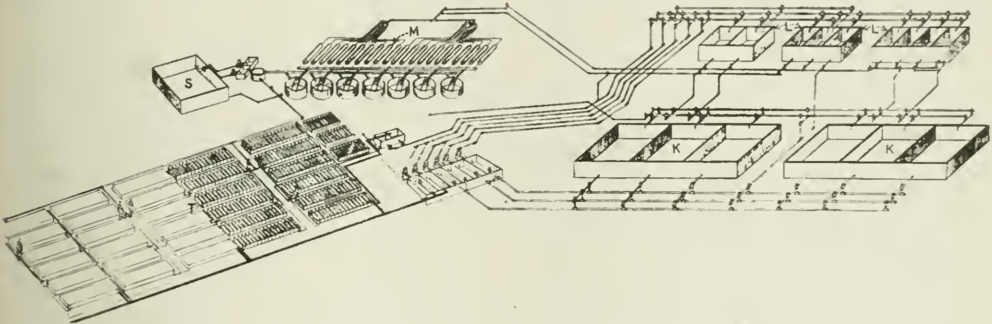

FIG. 2—PERSPECTIVE DIAGRAM OF LEACHING PLANT AT CHUQUICAMATA, CHILE

### Impurities in Solution

Of the impurities accumulating in the solution, the principal elements, outside of the chlorine present, are nitric acid, alumina, iron and alkali salts. After more than a year's work with the same solution, discarding only enough solution to take care of the excess acid, we find the following impurities present:

| | Grammes per litre |
|---|---|
| Fe | 3.71 |
| Mn | 0.07 |
| As | nil |
| Sb | nil |
| CaO | 0.80 |
| MgO | 3.32 |
| $Al_2O_3$ | 1.61 |
| $Na_2O$ | 21.60 |
| $K_2O$ | 5.00 |
| Nitric acid | 4.00 |

This amount of impurities is insignificant so far as effect upon the leaching and electrolysis is concerned.

The main impurity in our solution is the chlorine obtained from the salt in the upper part of the orebody. It was at first thought desirable to electrolyze direct the solution containing the chlorine and it was found perfectly feasible to do this in covered electrolytic tanks, maintaining a slight vacuum so that the chlorine gas was all drawn off through fans. However, it was also proven that only a part of the chlorine was eliminated in this manner and that an appreciable quantity was deposited with the cathode copper in the form, probably, of cuprous chloride.

### Elimination of Chlorine

Further experimentation proved that it was feasible to eliminate the chlorine from the solution by treatment with shot copper, the reaction resulting in the production of insoluble cuprous chloride. This precipitate settles readily.

Various methods of precipitating cuprous chloride were tried and finally shot copper, placed in a revolving drum, was adopted as the most satisfactory method. The cuprous chloride forming on metallic copper sticks tight to the copper shot, and it was found necessary to present continuously clean surfaces of copper in order to maintain an effective precipitation. After trying out several methods it was decided that the best apparatus for this purpose would be revolving drums similar to tube mills, through which the solution would be passed in contact with the shot copper contained in the drums, as in this way the copper, rubbing against itself, continuously presents a clean surface.

Precipitation with cuprous oxide gas also tried and worked very well except that the efficiency of the copper in this form as a precipitating agent, was found to be very much lower than that of metallic copper, even allowing for the theoretical difference.

The cuprous chloride produced may be treated in several different ways. It is our intention to filter-press the settled cuprous chloride, mix the filter press cakes with limestone and coke, and smelt the product thus obtained, producing metallic copper and calcium chloride as a slag. A number of experiments have been conducted with this mixture to establish the reaction, and it has been found that a very liquid slag of calcium chloride is produced containing a very small amount of copper, and that in this manner it is perfectly feasible to smelt the cuprous chloride without any loss by volatilization.

Some small scale experiments have also been made looking to the electrolytic treatment of the cuprous chloride and later on it may be possible that this latter method will be adopted, if found more profitable, in preference to the smelting method.

### Precipitation of the Copper

The solution, freed from its chlorine content, is now electrolyzed, using insoluble anodes and ordinary copper cathode starting sheets. After a vast amount of experimenting, we have decided to employ an insoluble anode made of magnetite. Various other anodes have been tried with more or less success, but after having investigated all the possibilities we have decided upon the magnetite anodes.

Experiments with these anodes have extended over about a year and a half, and we have found no material amount of chemical wear on the anodes. The magnetite anodes which we have adopted are manufactured by a secret process by the Chemische Fabrik Griesheim Elektron, of Frankfort, Germany. The nature of the material naturally gives a brittle anode. However, as it will not be necessary to handle the anodes after they are installed in the tanks, this is not a very decided drawback.

At first a number of difficulties were encountered in our efforts to secure an even current distribution and proper suspension of the anodes, but all of these obstacles have been overcome and we believe that a very serviceable anode has been developed.

The anodes themselves are hollow castings with a wall thickness of approximately ¼ in., and have a thin electroplated copper deposit on the inside.

As I am not myself familiar with the methods employed in the manufacture of these anodes, I am unable to give any further information on this point. I can only state that after months of continuous operation we have found the anodes entirely satisfactory for our purpose.

The copper cathodes produced from the electrolysis are of the usual quality of cathode copper—in fact, a little better—as in our particular case no arsenic or antimony, usually the most deleterious impurities in cathode copper, is present in the solution.

The solution will enter the head tank of the electrolytic system containing approximately 5 per cent copper and 2½ per cent to 3 per cent free acid, and will leave the last tank of the cascade containing about 1.5 per cent copper and 8 per cent to 9 per cent free acid. Within these limits it is always possible to produce a good hard cathode, equal to or better than the usual standard.

The electrolytic tanks used during our experiments are made of concrete, lined with mastic asphalt.

### Design of Plant now Building at Chuquicamata

On account of the very large ore body already developed at Chuquicamata the first unit of the plant now building has been designed to treat about 10,000 tons of ore per day. The electrolytic refinery will have a capacity of about 335,000 pounds of copper per day.

The ore will be mined by steam shovels, practically no stripping being necessary. The ore will be transported to the mill, distant about 2½ miles from the mine, in standard American gauge railroad cars of 60 tons capacity each.

Arriving at the plant, the ore will first pass through gyratory crushers, thence through 48-in. Symons disc crushers, and finally through Garfield rolls until a product is obtained of about ¼ in. mesh. The ore will be carried on conveying belts from the crushing plant, after sampling, to the leaching vats. Each of the leaching vats has the following dimensions, 110 ft. wide, 160 ft. long and 16 ft. high. The leaching vats, six in number, will be placed end to end.

The belt delivering the ore from the crushing plant will be discharged into the leaching vats with the aid of an electric traveling bridge, spanning and traveling the entire length of the leaching tanks. The leached and washed residue will be removed from the leaching tanks by a 15-ton grab bucket traveling on an unloading bridge and, after sampling, will be delivered onto a conveying belt for disposal to the tailings dump.

The tanks are being built of heavily reinforced concrete, and will be lined with mastic asphalt 1½ in. thick. This tank lining has been developed by the Vulcanite Paving Company of Philadelphia, and consists of a specially refined Trinidad asphalt mixture, to which is added crushed quartz or granite.

In our experimental plant, where this lining has been in use for considerably more than a year, both in the leaching and electrolytic tanks, absolutely no difficulty has developed—not even a single leak. We have tested the material at a temperature of 50 deg. C. without finding any signs of softening, and as this is far beyond the range at which we intend to operate tests at higher temperatures have not been made, although the temperature limit, so far as softening is concerned, will probably lie somewhere between 50 deg. and 70 deg. C.

Tests have also been made to try the strength of this material from a physical standpoint, and in one case a 250-pound cathode was elevated about 5 ft. above the bottom of the tank and then dropped in such a way that one of the sharp corners of the cathode hit the bottom of the asphalt-lined tank. In this case a piece of the lining about ⅛ in. thick and 2 ft. in diameter was broken away, and as far as we could see the tank lining was just as good as ever.

The material has been tested in strong and weak acid solutions and found to be absolutely unattacked.

From the bottom of the leaching tanks the solution will be removed through eight 6-in. openings equally distributed over the tanks. A filter-bottom, consisting of two layers of 2-in. planks with a layer of cocoa-matting between, will be employed. This filter-bottom will be raised 4 in. above the bottom of the tank.

For the main solution circuits, 9-in. and 16-in. lead-lined iron pipe will be used. Open-boot horizontal centrifugal pumps, made of type-metal, will be used for pumping the solutions. The pumps will have a capacity of 550 cu. ft. per minute, elevating to a height of 60 ft.

In the leaching plant the cycle of operation will require approximately six days, of which one day will be occupied in filling the tank, two days in leaching, two days in washing and draining and one day in discharging.

The solutions will be conducted to the leaching tanks by gravity from nine solution-storage tanks placed above the leaching tanks. The dimensions of these solution-storage tanks are as follows:

| | |
|---|---|
| Two tanks | 12 ft. x 130 ft. x 150 ft. |
| Seven tanks | 12 ft. x 70 ft. x 150 ft. |

From the strong-solution tank the solution will flow by gravity through the dechlorinating plant, consisting of twenty-one 30-ft. long by 4-ft. inside diameter revolving steel drums lined with earthenware. These drums will be half full of shot copper. From these drums the solution, containing the cuprous chloride in suspension, will flow to seven Dorr thickeners made of concrete and lined with mastic asphalt. The clear solution overflowing will travel by gravity to the electrolytic refinery, while the thickened cuprous chloride, together with approximately 1 per cent. of the original solution, will go to filter presses.

The electrolytic refinery will consist of 510 electrolytic tanks of the following dimensions: 19 ft. long, 3 ft. 6 in. wide, 4 ft. 10 in. deep. They will be made of concrete, lined with mastic asphalt, and will be set through the floor, having inspection aisles underneath and a concrete working platform between the rows of tanks. The tank-house will be of concrete and steel construction.

Of the 510 tanks, 30 will be used for making cathode starting sheets, and the balance, 480 tanks, will be used for electrolytic deposition of the copper from solutions. The tanks will be arranged in five electrical circuits, with 96 tanks to a circuit, and will be divided into 30 solution circuits, the solution in each circuit flowing through 16 tanks placed in cascade.

The anodes, made of magnetite, will be 5 in. wide, 2 in. thick and 4 ft. long, with five to a bar. The cathodes will be 3 ft. wide by 4 ft. deep.

The spent electrolyte, containing about 1.5 per cent copper, will be pumped back to the storage tanks to be used for leaching subsequent charges of ore.

The cuprous chloride from the dechlorinating plant will be smelted and cast into shot copper for use in the dechlorinating drums.

The power plant will consist of a primary power station at the coast, using oil-fired Babcock & Wilcox boilers driving four steam turbines, connected to four 10,000 kw. alternating current generators. The current will be transmitted 85 miles at 100,000 volts to a sub-station located at the mill-site. The sub-station for the electrolytic refinery will consist of seven motor-generator sets, each of 2,500 kw. capacity.

### Conclusion

It will be readily understood that a vast amount of experimental work has been conducted in order to arrive at a satisfactory solution of the problems before us in connection with the ores from Chuquicamata, and a great many negative results have been obtained as well as positive results. From fifteen to twenty young engineers have been continuously employed for more than a year on this experimental work, the experimentation going on steadily in three 8-hour shifts.

It has been our endeavor in conducting the experiments to operate each part of the apparatus on what we might term a cross-section scale of the plant to be erected at Chuquicamata. We have thus used a leaching tank with the full depth of ore column, the important point in leaching, and we have used the same material for filter bottoms as will be used in the large plant. We have had full size solution valves installed. In connection with the dechlorinating plant we built a full cross section drum. In the electrolytic tanks we have been operating with full size cathodes and anodes. In short the idea has been to approach in our experiments, as far as possible, operating conditions similar to those which we will have in the large plant.

I wish to take this opportunity to state that great credit for the results obtained should be given to the loyal and enthusiastic staff employed, and I will particularly mention in this connection Mr. C. A. Rose in charge of the experimental work at the plant, and his able assistants, Mr. Leonard M. Green, who, under Mr. Rose, has had charge of the leaching part of the experiments and who has developed the details of the leaching and washing system now adopted, and Mr. M. R. Thompson, who has had charge of the electrolytic part of the experiments.

---

**The Tulsa Spelter Company**, Sand Springs, Okla., had under construction in 1913 a 4000-retort plant. It is expected that operations will commence this month with 1600 retorts.

**Columbia University** has issued a pamphlet giving information regarding the new advanced courses in engineering and technical studies. From and after July 1, 1915, the Schools of Mines, Engineering, and Chemistry will become advanced or graduate schools, and candidates for admission will be required to show evidence of preliminary training equivalent to three years study in a college of scientific school of high rank.

## The Cost and the Advantages of Using Electrically Melted Ferromanganese

Electric steel furnaces of various types have found a new field of application in recent years, as they are being widely used in Europe to keep a molten supply of ferromanganese on hand at the converter plant. The use of molten ferromanganese instead of solid ferromanganese not only results in a saving of alloy, but makes the deoxidation more efficient and the steel better; and the cost of melting the ferromanganese electrically is more than counterbalanced by these advantages.

This method has been widely introduced during the last few years in Europe. The first plant to take up this practice in this country has been the Illinois Steel Company, which at its converter plant at Joliet, Ill., employs a 4-ton Heroult furnace to keep on hand a supply of molten ferromanganese from which 150 lb. are taken every seven minutes. It is the experience of this company that besides the saving in alloy there is a clear advantage in quality, the soft steel produced being decidedly better for wire purposes.

In Europe various types of electric furnaces have been employed for the same purpose, and the induction furnace has found particular favor in several plants. As very few exact figures have been published in the past on this subject the following results obtained in three European plants employing induction furnaces for melting ferromanganese should be of timely interest:

The three plants in question use for this purpose a 3-ton, 350-kw furnace, a 4-ton, 500-kw furnace, and a 4-ton 500-kw furnace respectively, all being of the three-phase, 50-period, three-ring Roechling-Rodenhauser type, the design of which is very well known to our readers.

In the plant using the 3-ton, 350-kw ferromanganese-melting furnace, some thirty to fifty tappings, ranging each from 90 to 120 kg (198 to 264 lb.), are made every twenty-four hours, depending upon the demands of the steel plant. For the first five weeks the average energy consumption, excluding the energy required for burning in the lining, was 721 kw-hours per ton for an output of 220 tons of ferromanganese.

To maintain the furnace hot during long intermissions 200 to 250 kw are required.

As a result of using molten ferromanganese, an average saving of 30 to 40 per cent of weight of ferromanganese required is recorded. With cold ferromanganese from 7 to 8 kg are used per ton of steel and during a year some 2100 tons of cold ferromanganese are required. With molten ferromanganese this amount is reduced to less than 1400 tons, representing a saving of more than 700 tons, which at $55 per ton represents a saving of $38,500 per year.

In one of the plants with a 4-ton, 500-kw furnace ferromanganese has been melted at the rate of 10 tons per twenty-four hours with an energy consumption of 750 kw-hours per ton. The furnace, however, is capable of melting a considerably higher tonnage of ferromanganese per day and when the demand of the steel works increases it may be expected that the specific energy consumption will be reduced.

At the same time the amount of ferromanganese used per ton of steel has been reduced at this plant from 7.5 or 8 kg (for cold metal) to 4 kg (for molten metal), which is a saving of from 45 to 50 per cent.

If the results of these two furnaces are used on which to base an estimate of the power requirement and savings to be expected in new installations, it seems safe to figure on a saving of 30 per cent in weight of ferromanganese and a power consumption of 675 kw-hours per metric ton of ferromanganese for a 3-ton furnace in regular operation. For burning in the lining and heating up a 3-ton furnace about 3500 kw-hours are required and a life of 12 weeks, or 84 days of twenty-four hours, may be expected for the lining. From these data a figure for an additional small power consumption may be deduced. As stated, all these figures refer to induction furnaces. It would be interesting to get for comparison data from arc-furnace installations.

The use of molten ferromanganese has, however, additional advantages which cannot be stated as easily in figures. Owing to the rapidity with which molten ferromanganese becomes distributed through a steel charge much time is saved owing to the fact that the steel may be teemed at once. Further low-grade ferromanganese, containing large percentages of fines, may be easily melted in an electric induction furnace.

That the quality of the steel is improved by the use of molten ferromanganese will be understood from the following considerations:

The deoxidizing effect is much stronger and more rapid than with solid ferromanganese, as the latter must first be dissolved and exerts a certain cooling effect.

As the ferromanganese is added to the steel while teeming, it does not come into contact with the slag, and rephosphorization by reduction of the phosphates in the slag is entirely excluded.

Frequent analyses in the three induction furnace installations in question have proved that the composition of the steel remains constant from the first to the last ingot for any one charge.

On account of the uniformity of the composition of each ingot due to the better distribution of manganese and also to the more complete deoxidation the steel "rolls" extremely well. It has been proven that a section which, when cold ferromanganese was used, could not be satisfactorily rolled with steel containing less than 0.4 per cent Mn, can, when molten ferromanganese is used, be rolled easily from steel containing only 0.29 per cent Mn.

The amount of ferromanganese per ton of steel can be considerably reduced on account of the certainty that the total amount of ferromanganese added is utilized and nothing is retained in the slag or remains undissolved in the steel.

The contents of the ladle can be poured at once whereas much time is saved and, moreover, the charge need not be so hot from start so as to be able to heat the ferromanganese to melting temperature. The liquid steel remains completely quiet, does not boil, and can be poured very satisfactorily.

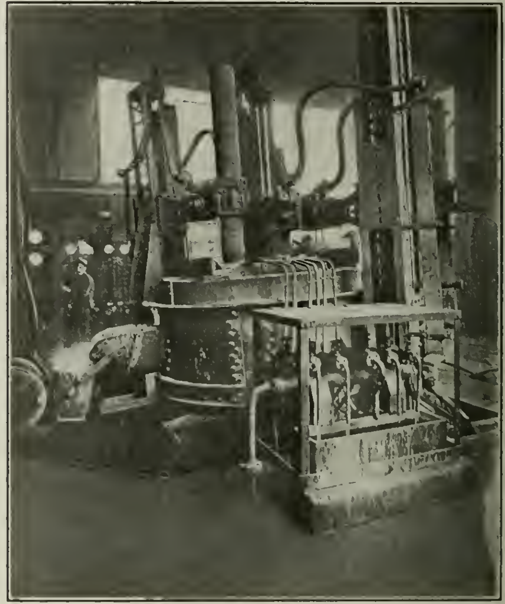
The lining is put into ferromanganese induction furnaces in about the same way as in steel furnaces; that is, a mixture of magnesite, or dolomite, with tar is rammed in hot. But because the temperature required is not so high as for steel and also because ferromanganese is usually in particularly convenient form for melting in an induction furnace, the life of the lining is much prolonged. From the results so far obtained it is thought possible when working continuously to average between four and five renewals per year, or even better.

No slag is required. The molten metal is effectively protected from oxidation by a layer of carbon in the form of petroleum coke. The metal being saturated with carbon, no alteration in composition occurs. The fact that such a covering is used proves that the atmosphere in the furnace is non-oxidizing.

While, as stated before, the Roechling-Rodenhauser type of combination induction furnace is used in the three installations here discussed, the Siemens & Halske Company, which made these installations, has developed more recently an improved type of induction furnace which combines the good points of the Kjellin, Roechling-Rodenhauser and Frick types and with which it has been possible to reduce the specific energy consumption still further.

* * * *

While the data given above from European practice refer to plants using induction furnaces for melting ferromanganese, other types of electric furnaces are also used for this purpose in Europe. The adjoining illustrations show a five-ton Girod furnace recently installed by the Friedrich Krupp A. G., Friedrich-Alfred Hütte, Rheinhausen-Friemersheim, Germany, for the melting of ferromanganese.



ELECTRIC FURNACE FOR MELTING FERROMANGANESE AT KRUPP PLANT

## Salt Lake City Meeting of American Institute of Mining Engineers

The one hundred and eighth meeting of the Institute will be held at Salt Lake City, Utah, August 10 to 14, 1914, inclusive. Local committees have been active in preparing for the entertainment and convenience of visiting members and an excellent technical program has been provided. Twenty-five papers have already been accepted for this meeting and others are expected. Authors are urged to have all papers in the hands of the secretary by May 15 if possible, and not later than May 31. Papers will be printed and distributed in advance to those members desiring to prepare discussions.

The social features of the Salt Lake City meeting will include visits to the neighboring mines and metallurgical works at Bingham Canyon, Garfield, Lark, Murray, Midvale, Park City and Tintic.

Adequate provision is being made for the comfort and entertainment of ladies, and a special committee has been organized to take care of this part of the meeting.

# Is There A Complex-Ore Problem?

## A Symposium on the Economics and Metallurgy of Mixed Base-Metal Sulphide Ores, Showing Present Status and Future Prospects of This Branch of Ore Treatment

A great deal is being said these days about "complex ores" and the "complex-ore problem," having reference to mixtures of base-metal sulphides and their profitable treatment. The impression prevails in some quarters that these ores are not amenable to present methods of treatment; that there are "millions of tons" of such ores; and that there is a distinct need for new treatment processes. In order to get a broad view of the real situation, and to ascertain to what extent the above impressions are correct, we invited a number of competent metallurgists and engineers to join in a symposium on the subject. The response has been gratifying, showing as it does a keen interest in the subject, and presenting a number of points of view. We give herewith a part of the contributions received and will present further views in our next issue. When all the views have been published we shall give a résumé of the situation as reflected from different engineers in various parts of the country.

In order to direct the line of inquiry we submitted a list of questions, which appear below, to serve as a general guide in approaching a subject which is admittedly broad and comprehensive. The reader will observe unanimity of opinion on some points, and diversity on others; all are interesting.

1. Is there a "complex-ore problem," and what, in your opinion, constitutes a "complex" ore?
2. Would such ores be amenable to present methods in the hands of skilled operators, or is there a need for new methods of treatment?
3. Do you believe there are many mines now idle which could produce a considerable tonnage of such ore if suitable methods of treatment were known?
4. What element or quality of such ores makes them refractory to present processes?
5. What methods or processes do you regard as probable solutions of the problem (mechanical, hydrometallurgical, electrometallurgical)?
6. To what extent would microscopical examination of such ores be of material assistance in suggesting proper methods of treatment?

**W. G. Swart:**—1. Yes, there is a complex ore problem in the sense you intend the inquiry, "complex ore" meaning a sulphide mixture. It would perhaps be better to say that there are complex-ore problems, because neither ore bodies nor treatments therefor are twice alike. This rather important fact, often overlooked, makes it difficult to say yes or no to all your questions without qualification.

2. By far the greater part of such ore can be successfully handled by mechanical methods, such as concentration, flotation and separation. "Successfully" in this instance means "profitably." Results are always better where skilled operators are employed. Failures may usually be traced to unskilled financing, engineering or operating. No one claims that mechanical methods are perfect or broadly economical, but they pay dividends. Some ores now in sight cannot be treated by mechanical means. Such ores must await new methods.

3. Not many mines containing complex ore are idle because of lack of suitable metallurgical processes. Idleness is due more to such conditions as inaccessibility, heavy snow, poor transportation, high freight rates, high fuel, distance from market, lack of water, poor financing, bad management, ignorance, and improper mining and milling methods. The complex-ore bodies of America, with two or three notable exceptions, are small, scattered and dissimilar, and this is the real complex-ore problem. It must be solved not generally, but each case individually.

4. I should say that fineness of crystallization, while not the sole cause of "complexity," probably causes the most trouble to mechanical processes.

5. Mechanical methods will hold their own for some time to come because results and costs can be safely and closely predicted from experiment and because small economical plants are possible for small ore bodies. Plant cost on most of the proposed chemical and electrical methods is prohibitive for small mines. Central custom plants like the present lead and copper smelters may eventually be established, but this will still leave the low-grade, inaccessible mine without an outlet.

6. The microscope always has helped the metallurgist and always will. The difficulty here is again the danger of generalization. Each ore will have to be separately studied and its proper mechanical treatment worked out. It is no uncommon experience to find today's mill supply from the second level a very different ore and problem from yesterday's tonnage from the fourth level. It by no means follows, either, that mixing the two for an average feed gives the best results.

My general conclusions are that the problem is not one of processes so much as one of economics of mining—the location, size and character of the ore bodies. Show the metallurgist the ore and he will successfully treat it, *if there is enough of it.*

Denver, Colo.

**Robert N. Bell:**—There is a "complex-ore problem." As to what constitutes a "complex" ore, I would say that I have a deposit in mind, where a considerable tonnage is available, in which the ore consists of zinc-lead-iron sulphide forming an amorphous blend, with absolutely no crystalline grain except scattered crystals of pyrite that contain equal proportions of lead-zinc-iron sulphides. There is hardly any gangue material. The ore breaks with a conchoidal fracture, and has a grain like broken steel. Some able metallurgical talent has tried to separate the more valuable minerals in this ore, but without results worth speaking of. Of course, it could be smelted, but the zinc would be wasted and the lead would not carry the cost of shipment and treatment. A similar condition prevails in less degree in a fine-grained crystalline ore from the Morning mine, at Mullan, Idaho, where successful advances have been made in separation through improved flotation methods.

As an example of refractory ore I would cite one which is a solid mass of arsenical pyrite, almost grainless in texture. It constitutes about 60 per cent of the ore-body, and contains about 6 per cent lead, 12 per cent zinc and 6 oz. silver per ton, the latter associated with the lead. This ore has resisted all attempts at separation by leading metallurgists, but is now undergoing further experimentation.

In my opinion, hydrometallurgical and chemical means will have to be employed for the successful treatment of such ores.

Microscopical examination has been of material assistance in the advances made in treating ores from the Coeur d'Alene (Idaho) district.

Boise, Idaho.

George E. Collins:—I. I suppose a "complex ore" is any ore which contains several valuable metals which have to be separated, or partly separated, in order to obtain marketable products. Accepting such a definition, there would be as many "complex-ore problems" as there are complex ores. Popularly speaking, complex ores are mixtures of zinc sulphides with lead, iron or copper sulphides.

2. Such ores are amenable to (imperfect) separation by known methods, or combinations of methods, but usually with partial success, because of the losses incidental to separating and marketing. In other words, but a small portion of the gross value of the metals contained is received by the original producer of the ore. The other methods proposed, such as electric smelting, chlorination and various forms of leaching, have not been sufficiently tried out under actual working conditions to justify positive conclusions as to their scope, or to enable the metallurgist to figure on the commercial results to be realized from them. They are as yet possibilities (or probabilities), rather than practical processes.

3. There are great numbers of mines now idle which could produce a large aggregate tonnage of complex ores, if it were commercially remunerative to apply known methods, or combinations of methods, or if other methods were available which could be successfully applied in small and inexpensive units.

The greatest difficulty is the small size of the orebodies in the vast majority of mines; which will warrant neither venturing experimentally into new metallurgical fields, nor even the installation of known processes, calling for expensive equipment. The majority of mines are small, and their life uncertain. Mines which will produce large tonnages are rare, equally when the ores are complex, as when they are simple.

So far as I know, there are few deposits now unworked of sufficient magnitude to justify experimenting with such processes as electric smelting or chlorination; which, even if eventually successful, are likely to be expensive luxuries for the pioneer. The details of such processes should be worked out by large existing producers, or by associates of such producers. Perhaps this might even be a proper field for the activity of the United States Bureau of Mines, in view of the possible value of these methods in aiding the conservation of the mineral resources of the nation.

4. I do not know of any "element or quality" of complex ores as above defined which "makes them refractory to present processes," excepting, perhaps, the tendency for the constituent minerals to be closely interlocked with each other, and in some cases with gangue of similar specific gravity. It is mainly a matter of costs and market values.

5. At present, I think we are dependent on mechanical ore-dressing methods, with flotation as an alternative; in either case supplemented by magnetic or electric separation.

Eventually, I believe that electric smelting, along the lines suggested by Johnson, will be feasible, and perhaps also chlorination and leaching. The two former I think will usually be applied to ores on which a rough preliminary dressing has been made by flotation or concentration, for I cannot conceive of the costs being low enough to warrant omitting preliminary treatment. For the moment, not having been sufficiently tried out to afford definite data as to field for successful application and costs, they are outside the sphere of the engineer, but may enter it before long, especially in districts where cheap power is available.

6. Microscopic examination, with low power, is of great value in mechanical concentration, and also in electrostatic work. In both these lines it may be regarded almost as a standard practice. I do not know in what way it can be of value in solvent or fusion metallurgical methods.

Denver, Colo.

G. H. Clevenger:—There are, in non-ferrous metallurgy, a number of "complex-ore" problems, and inseparably associated with them, and towering above them, and of even greater importance, there is a low-grade problem. The metals can be recovered from all ores by known processes; but it is not always possible to do so at a profit. The demand for the metals and the exhaustion of many of the higher grade deposits, together with the economic necessity of producing them at a profit is responsible for the "complex" and the low-grade ore problem. There is also the ever-present possibility of recovering the metals at a still greater profit from ores now being profitably treated. Call this problem what you will, so long as the percentage of extraction is below 100 and the working costs are greater than 0 the metallurgist has it staring him in the face.

The term "complex ore" is used in so many ways that it is difficult to give a single definition which will hold in all cases. It at once conveys to the metallurgical mind an intimation of difficulties to be met and overcome. In the most general sense a "complex ore" would be one the constituents of which, and their occurrence, were such that the metals could not be readily recovered from it by ordinary methods of treatment. The extreme case would be one in which the ore cannot be treated by any known process at a profit. An ore ceases to be "complex" when difficulties connected with its treatment are satisfactorily overcome. For some time metallurgists have associated the "complex" ore problem more particularly with ores containing zinc associated with other metals.

All ores are amenable to present day smelting processes as applied for the recovery of the more common metals, copper, lead, gold and silver. This comes about not only through the flexibility of the smelting operation, but also through the present-day practice of locating large smelting establishments at railway centers, which makes possible the blending and mixing of a variety of ores. Thus, if one ore contains a high percentage of some objectionable element it is diluted by smelting with other ores. The large smelting interests located at central points, where they can draw ores from a number of districts, therefore known nothing of the so-called complex ore problem as regards these metals. True it is that they have their troubles, and that some ores are more easily treated than others, but notwithstanding this all ores containing copper, lead, gold and silver in payable quantities can be satisfactorily treated.

Zinc is troublesome in the smelting operation for the other metals, but as has been mentioned, even this difficulty is readily overcome by smelting very zincky ores with ores which are low in zinc, so the total mixture does not contain zinc in excess of that which can be economically handled in the smelting operation. While it is true that zinc does not prevent these other metals from being recovered, at the same time, with present-day smelting methods all such zinc, with the exception of the small amount recovered by the bag house, as in the Lewis and Bartlett process, is lost in the slag and the fume. Herein lies one of the greatest weaknesses of our present day smelting practice, in that there is a distinct economic waste going on as regards zinc, much of which will never be recovered. It must be conceded that sooner or later we must look to these sources for a large portion of our zinc supply. Therefore, this problem is of constantly growing interest, and judging from the amount of effort which has been expended upon it in the past few years, and is now being expended upon it, a satisfactory solution is not far distant. Therefore, as regards complex copper, lead, gold and silver ores, which are commonly known as smelting ores, the great problem is the recovery of zinc, and to a less extent other by-products.

In this connection I have in mind a California mine which for a number of years operated profitably, recovering copper and the precious metals by the ordinary copper smelting process. The zinc contained in this ore, which was entirely lost in the smelting operation, calculated at the ordinary market price for zinc, had a greater value than the other metals combined. If there were a satisfactory process for recovering zinc in conjunction with the other metals, this mine could greatly augment its present profit.

Much has been accomplished in solving this problem by separating a marketable zinc product by various concentration methods. Hydrometallurgical processes for the recovery of zinc have been beset with many difficulties and although an enormous amount of money has been expended in their exploitation, there is at present no plant in regular commercial operation which employs a process of this type. Electrothermic processes have received their share of attention, but opinion differs regarding their commercial applicability. Here the problem seems to be in the condensation of the zinc vapor.

When an ore contains too small a proportion of the valuable metals to render its shipment to a smelting plant for treatment profitable, the next possibility becomes local treatment. This may take the form of concentration, which produces a product of high enough grade to ship; and thus a profit is derived from an ore which otherwise could not be treated. In the past this has been the only alternative with low-grade copper and lead ores, but at present there are a number of hydrometallurgical processes for low-grade copper ores which are being rapidly developed.

For years the ordinary process of plate amalgamation for the recovery of gold has been practiced in the most remote of mining camps. It is perhaps the simplest and cheapest of metallurgical processes but it is suited only for the recovery of gold occurring in the native state. While little more could be desired of a process in point of simplicity, yet as ores have changed in character through the discovery of new occurrences, and the attainment of greater depth upon the old deposits, simple ores became "complex" ores as regards plate amalgamation.

These ores therefore presented the low-grade ore problem as regards smelting, and the complex-ore problem as regards the simple process of amalgamation. The cyanide process practiced either singly or in combination with other operations as amalgamation, concentration, roasting, etc., has done much to solve the low-grade ore problem of smelting and the complex-ore problem of amalgamation, as regards gold and silver ores. But complex-ore problems have arisen in the operation of the cyanide process; for example, suppose we have an ore containing some copper, in which gold and silver predominate, which cannot be profitably smelted. If there is a sufficiently high percentage of copper in the soluble form, such an ore cannot be cyanided on account of the copper, which not only interferes with gold and silver extraction, but also causes a prohibitive cyanide consumption. The inability to treat gold and silver ores containing copper is today one of the weak points of the cyanide process, and may be said to be one of its "complex-ore" problems. Another "complex-ore" problem of the cyanide process is a most perplexing difficulty which arises in connection with the application of the cyanide process to the treatment of certain silver ores. This problem is not, as many have supposed, associated with the treatment of the unoxidized or lower-level sulphide ores, but is a result of oxidation either through natural causes during or after ore deposition, or of oxidation artificially induced as in the oxidizing roast. This difficulty frequently arises in treating ores containing the oxides of manganese and the manganese has therefore frequently been held to be the culprit; but there are reasons for believing that the silver is not in combination with the manganese in such cases.

The lack of a skilled operator will cause the failure of any process; but as there is no lack of skilled operators for all metallurgical processes, the owner has no one but himself to blame if his metallurgical ship goes aground on this shoal.

The mining engineer is best qualified to answer the question regarding the amount of complex or low-grade ore which mines now idle could produce. Judging from what I myself have observed and from what mining engineers of extensive experience have told me, the amount of such ores awaiting a satisfactory process of treatment has been greatly exaggerated. It is no unusual thing for tremendous deposits of two and three-dollar ore to shrink into nothing upon careful examination. Therefore the legitimate complex and low-grade ore deposit must be carefully sorted out from the many supposedly valuable deposits awaiting satisfactory methods of treatment. The first step in an investigation of this kind is to retain a competent mining engineer. Frequently he will be able to complete the investigation without the aid of the metallurgist.

Although the mechanical side of metallurgy has reached a very high stage of development, unquestionably far in advance of the chemical side, one would scarcely venture the opinion that there was nothing further to be accomplished in this line; but it does seem probable that the most important developments of the future will be made upon the chemical side of the subject.

There have been a great variety of electrometallurgical processes tried on a commercial scale in the Western mining states; but the performance in most cases has been disappointing. Notwithstanding previous failures there are many of us who still hope for important developments in this direction, but it is impossible to predict along just what lines.

Hydrometallurgical processes are of rapidly increasing importance and in the course of time they will take first rank for the recovery of certain of the other non-ferrous metals, as they have done with gold and silver through the cyanide process. This seems to be particularly true of copper. The incentive for this development is due, on the one hand, to the high losses of metal occurring with present-day concentration systems, as applied to the treatment of the low-grade ores; and on the other, to the increasing difficulties with the smelter-smoke problem. It is my belief that one great solution of the smelter-smoke problem, as well as of overcoming the trying losses which occur in the concentration of low-grade copper ores, will be the operation of a hydrometallurgical process or processes, which will recover directly a high percentage of the copper without disturbing sulphur, arsenic, etc. When this happy day arrives, we will take out the valuable constituents of the ore without in any way altering the objectionable gangue minerals. After all, the best solution of the vexatious smelter-smoke problem is not to make the smoke. Are we hoping for too much, to expect that in the future a solvent will be found for copper in its common combinations, which will remove the copper from most ores regardless of whether the gangue is largely silicious or basic, and without disturbing the major portion of the sulphur and arsenic? I think not. Consider what is now an accomplished fact through the cyanide process with gold and silver ores. It is now possible in most cases to treat concentrates containing gold and silver, consisting largely of the sulphide minerals, more economically than they can be smelted and without disturbing the sulphur. The sulphur goes onto the dump in the form that it came out of the ground, minus the gold and silver. Every day we hear of a new application of this process, even to very complex ores which it was formerly thought were either too complex or too high-grade to treat by such methods, therefore must be smelted. Perhaps the most convincing argument in this line would be to refer to what has been accomplished in treating the high-grade ores of the Cobalt district, where ores which carry approximately 39 per cent of arsenic, together with many other impurities, and on an average about 10 per cent of silver, are today more economically treated by a hydrometallurgical process than by smelting, and without contaminating the atmosphere with arsenic. I do not wish to be understood as predicting that the smelting of copper ores will be entirely supplanted by hydrometallurgical methods, for there doubtless always will be cases where hydrometallurgical methods cannot be applied to the best advantage; but the extensive development of hydrometallurgical methods is going to prove a solution of some of our present-day ore-treatment problems.

Microscopical examination will eventually have its place in the working out of the problems of ore treatment, but just at present there is a serious difficulty in its application on account of the fact that the specific effect of the various minerals has never been thoroughly worked out for the different processes. However, it must be remembered that at best microscopical examination would only assist in locating the difficulty, and that the major portion of the problem lies in finding and applying the remedy.

Palo Alto, Calif.

**H. A. Guess**:—1. There always is a complex ore problem, but of late no doubt more prominence is given to it as the simpler ores get scarcer. A complex ore from the ore-dressing viewpoint is one difficult to separate into marketable products, either because the minerals of the different valuable metals are too intimately and finely mixed, or are of about the same specific gravity, or have a gangue or a portion of it, of about the same specific gravity as the minerals.

2. It is doubtful if the present processes, even the newer ones, will satisfactorily treat the more difficult of these complex ores.

3. There are, no doubt, some mines now idle which could produce a considerable tonnage of such ores if suitable methods of treatment were available.

4. The cause of refractoriness has been touched upon in 1.

5. Each of the three types of processes you list will doubtless contribute toward successful treatment of difficult ores.

6. Where the minerals are very finely and intimately mixed, microscopic examination of the fine screen sizes, say of tailings, often aids in showing how fine it is necessary to crush to effect complete liberation of the minerals.

New York City.

**F. W. Traphagen**:—1. There certainly is a "complex-ore problem." Complex ores are: First, ores containing several metals in such intimate mixture that direct smelting or ore-dressing methods are inapplicable, and in which no one or more metals can be sacrificed commercially for the recovery of the others. Second, ores in which the losses by dressing methods are so great, because of the production of rich slime, or tailing, or mixed concentrate, that ordinary methods of treatment would yield little or no profit. Third, ores from mines so situated geographically that the ore or concentrate therefrom would yield no profit because of high freight and treatment rates.

2. Undoubtedly improvement could be made in present practice by skilled operators, but there is not as much room for progress in present methods, particularly mechanical processes, as in the development of new methods.

3. There are undoubtedly many properties that would yield large tonnages of ore that cannot be handled under existing conditions, if suitable methods of treatment were developed.

4. No particular element is responsible for the refractory nature of complex ores. Zinc is objectionable in lead and copper smelting for several reasons, and, in addition, is completely lost in those operations. Lead is not saved in modern copper smelting practice. The difficulty in treating complex ores lies in the fact that our metallurgical processes save but a few metals and sacrifice others of value. This is the principal phase of the "complex-ore problem."

5. The solution of the problem lies in the development of some method involving a combination of hydro- and electrometallurgical practice. The process should be applicable at or near the mines, and produce metals of products of sufficient purity to be marketed at once, without the necessity of sustaining additional charges to make them sufficiently high grade to market.
